

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

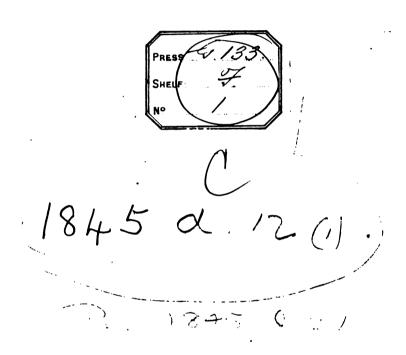

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + Refrain from automated querying Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at http://books.google.com/

PREFATORY NOTE.

The objects of the series of papers of which the publication is commenced in the present volume, are, a systematic determination of the constants of astronomy from the best existing data, a re-investigation of the theories of the celestial motions, and the preparation of tables, formulæ, and precepts for the construction of ephemerides, and for other applications of the results. The adopted policy, which is more fully set forth in the Introduction, contemplates the subdivision of the work and the publication of each part as soon as completed, in such a way as to render easy the subsequent combination of the whole.

It is not intended to include any papers in the series but such as conduce to the objects in view.

INTRODUCTION.

It is well known to all astronomers who have given attention to the subject that meridian observations of the moon and planets are not completely represented by any of the existing tables, and that the deviation of prediction from observation is constantly increasing. It is true that, so far as the current requirements of astronomy are concerned, the state of the case may be considered as not unsatisfactory. Not only may the planets be found and eclipses predicted for many years to come by the present tables, but, with the exception of the moon, there is every reason to suppose that the tabular positions will serve the purposes for which they are immediately required in navigation and practical astronomy. But when we take a wider view and consider the general wants of science both now and in the future, we find that in the increasing discordance between theory and observation there is a field which greatly needs to be investigated.

If mutual gravitation according to the law of Newton is the only cause which changes the motions of the planets, then it is mathematically possible to construct tables which shall represent observations with the last degree of precision and through any period of time. It is quite possible that the discordances alluded to proceed solely from the imperfections in the mathematical theory, and do not indicate any unknown cause affecting the celestial motions. But when we investigate more closely, and seek to ascertain the cause of such discordances, we find a state of things which renders it impossible to draw any definite conclusions respecting the ultimate possibility of representing observations by existing physical and mathematical theories. This state of things has its origin in the comparative brevity of the period during which accurate observations have been made, and in the difficulty of conducting, on a systematic plan, mathematical investigations having in view the perfection of astronomy.

One point in which the requirements of astronomy differ from those of physics is that the element of time enters into the former much more than into the latter. The experimental investigation of forces which act on the surface of the earth requires only the time necessary to make and perfect the experiments. There is no one research of which we can say that it will necessarily require a definite number of years or centuries for its completion. But since astronomical generalizations rest, not upon experiments, but upon observations, it is always necessary to wait for the recurrence of the phenomena on which the conclusions are to depend. The main object of investigation being the forces which change the motions of the planets we must observe these motions during a sufficient period to make evident the action of the forces. The longer the time which elapses the more material we have for reaching conclusive results. It is generally considered that accurate observations commenced with Bradley in the

middle of the last century. The period during which they have continued is therefore about a century and a third. But there are many exceptions in the case of different classes of observations. The places of the moon have been traced backward with a nearly modern precision through the century preceding Bradley's observations, while the observations of the Babylonians and the Arabs are still of the greatest value in the lunar theory. On the other hand none of Bradley's instruments fulfill the requirements of the present time, and his observations were in many cases extremely defective as compared with our own. If, therefore, we attempt to learn what conclusions can be reached in the present state of astronomy we must consider each object of observation separately with reference to its general place in a comprehensive scheme.

But time is not the only element which comes in. If we are to determine what unknown causes affect the motions of the planets the first step is to prove that there is really a discordance between the results of observations and the results of the theory of gravitation. The first step towards establishing such a discordance is the construction of tables and formulæ of which we can say that they are beyond reasonable doubt the results and the only results of the gravitation of the known bodies of the solar system. The necessary conditions which such tables and formulæ must satisfy are that they shall be founded upon uniform elements and data, and that the results of employing the adopted elements shall be carried out with all necessary precision. Now, not only has this requirement never been fulfilled, but the effect of recent advances in exact astronomy has rather been to carry us away from its fulfillment.

It is scarcely possible for a year to pass without some new investigation or series of observations which shall materially add to the precision with which we can determine some astronomical constant. Each astronomer who finds material to be used in this way is naturally desirous of utilizing it to its fullest extent, and is therefore under a temptation to introduce each new improvement into his investigations without respect to their consistency with the investigations of others which have been made with the older data. Sometimes, too, the object of constructing an astronomical formula is to correct it from time to time, and the very object of the constructor may tend to destroy its consistency. A brief glance at some features of the existing planetary tables will illustrate the point in question.

LAPLACE, in the third volume of his *Mécanique Céleste*, constructs, by the most rigorous and complete methods then known to science, a complete theory of the planetary perturbations, founded on elements and masses which are quoted in Chapter VI of his work. From his results tables were constructed by LINDENAU and BOUVARD during the early years of the present century.

In order to give the tables the required precision it was necessary to correct the elements by a comparison with observation. Thus, the new tables no longer corresponded to the original formulæ of Laplace. Moreover, the theory was in many respects so imperfect that no certain conclusion could be drawn from a comparison with observation. This was notably the case with the perturbations of the second order. It was therefore necessary to make a complete reconstruction of the theory. Nevertheless, such was the labor and difficulty of constructing new tables that those of

LINDENAU and BOUVARD remained the standards for use in the preparation of ephemerides during nearly half a century.

The next complete reconstruction of the theories and tables of the planetary motions was that of Leverrier. His work on this subject forms the most important part of the fourteen volumes which he published under the title *Annales de l'Observatoire de Paris*. The first of these volumes appeared in 1855, the last in 1877.

Some consideration of the circumstances under which this great work was carried out and of the objects at which it aimed may not be out of place as showing how it happens that more remains to be done in the same direction. When LEVERRIER commenced his work, the most striking feature which presented itself was the imperfections of the tables of LINDENAU and BOUVARD. The formulæ on which they were constructed, though fully up to the science of the time in which they were formed, was far behind modern requirements in generality and rigor. Better tables and formulæ constituted one of the most pressing wants of exact astronomy. Both his position and his previous works marked Leverrier as the one to undertake the work of constructing such tables and formulæ. Naturally desirous of beginning to reap the results of his labor as soon as possible, he investigated the elements of the planets and published the corresponding tables one or two at a time. This course did not detract from from his main object, that of constructing improved planetary tables. But there was another object, the desirableness of which was not immediately felt, but which must be more and more felt in the not distant future, namely, the attainment of uniformity in adopted astronomical data. So far was Leverrier from aiming at this object, in its entirety, that his tables do not, in all cases, embody his final results. The consequence is, that notwithstanding that his work makes a greater epoch in astronomy than any of his immediate successors can hope to make, it does not wholly supply the wants of science in the immediate future. In many of his tables large and increasing deviations from observation already exhibit themselves. This is most notably the case with the planet Saturn, the theory of which he did not succeed in bringing to a satisfactory conclusion. The geocentric places of Mars and Venus are also largely in error at the time of nearest approach to the earth. The earlier tables, those of the Sun and Mercury, are the only ones which can be regarded as entirely satisfactory in their agreement with observations, with the possible exception of Uranus and Neptune.

What has been said of Leverrier's tables applies with yet greater force to the tables of Uranus and Neptune by the present writer. Their main object was to supply an immediate astronomical want. The data on which they were found could not be regarded in any respect as definitive, nor were the adopted masses absolutely uniform. The formulæ of perturbations on which they depend are also such that we cannot say with certainty whether the deviations from observations which they exhibit arise from any other cause than the imperfections of the theories on which they are founded.

Now, the material available for the accurate determinations of the fundamental elements of astronomy has increased many fold since the conclusion of LEVERRIER'S work on the four inner planets. The recurrence of transits of Venus and Mercury, the perfection of astronomical instruments, the employment of improved places of the fixed stars, the introduction of more systematic methods of research, and the rein-

1

vestigation of older observations have all combined to bring precise astronomy to a higher plane than it ever before occupied. Supposing that their mutual gravitation is really the only cause which disturbs the elliptic motion of the planets around the sun, it is now theoretically possible to construct tables of all the large planets, except Neptune, from exact data, which shall represent observations within their probable errors until the middle of the next century. The desirableness of having such tables founded on one consistent and fully elaborated theory, hardly needs to be insisted on. Only in this way can it be decided whether deviations from theory arise from its imperfections, or from the action of unknown and, perhaps, unsuspected causes.

A more detailed survey of the field will bring to light other reasons for placing the results of past observations and researches in such a form that they may be utilized in the future.

We first remark that the existing data in the form of observations lie in great part unused, and are in danger of never being used, unless discussed and condensed in such a way as to render them manageable. Long series of observations made during the present century by eminent astronomers, and with the best appliances, lie idle in the volumes which embody them, never having appeared in any of the existing tables. In order to be utilized to the best extent they need to be rediscussed by modern methods and with modern places of the fixed stars. The labor of doing this is such that we only find it performed in sporadic cases by individual astronomers. One of two courses must now be adopted. We must either suffer this great mass of material, collected in many cases by the life labors of eminent observers, and published at great expense, to go to utter waste, or we must speedily put it in a shape to be utilized for present and future purposes. It is true that if nothing were to be added to the mass we might safely leave it in confidence that future astronomers would give it more attention than we have. But so rapidly does it increase that it is even now entirely beyond the power of individual management, and the longer it is left the less hope there is that it ever will be managed. The required work must be that of an organization rather than that of an individual. All that the head of an organization can do is to plan the work, investigate the formulæ and data by which it is to be done, devise the checks which are to guard against error, discuss the results, arrange them for the press, and see that every operation is conducted on correct principles and by the best methods.

Not only should the work be founded on all the observations which it is practicable to employ as its basis, but a necessary feature is a utilization, so far as possible, of all discussions by other astronomers. Although the work may become less individual in character, it has greater claims to consideration on the score of embodying the labors of the leading astronomers of the time.

On assuming the superintendency of the American Ephemeris in 1877, the writer determined to employ the resources at his disposal to carry out, or at least to enter upon, a long cherished plan of executing the work in question. No published announcement of his programme was, however, made, owing to the ease of making such a programme alongside the difficulty of executing it. There are, however, two reasons for no longer maintaining this reserve. One is that although what has been done is

only a commencement, the prospects of being able to carry it through are fairly good. Both Congress and the Navy Department have supplied all the assistance which has been asked for, and a force of from eight to twelve computers, some of the highest order of mathematical ability, has been actually employed during the past year, and may, if necessary, be increased in the future. Another and more cogent reason for announcing the programme is that much duplication of work may thus be avoided. Astronomers in other parts of the world are from time to time undertaking investigations already in hand and sometimes announce their intention in private correspondence where nothing has appeared in print.

This remark is not made to discourage such attempts, because, owing to the magnitude of the work, it is desirable to utilize all investigations, wherever made, which will in any way contribute to its completion. It is, however, essential that such investigations should be made in such a way as to adapt themselves to the general plan, and that they should be completed so far as practicable. With a view of enabling those interested to form the best judgment of the situation a statement of the unpublished work now in hand, with a general programme for its continuance, is here presented.

The theories of the four inner planets naturally claim the first attention as embodying most of the fundamental elements of astronomy. This branch of the work includes not only the masses of the planets and the elements of the respective orbits, but the constants connected with the rotation of the earth on its axis, namely, the annual precession, the obliquity of the ecliptic and its secular variation, the position of the equinox among the stars, and, indirectly, the positions of the fundamental stars. To these may be added the solar parallax and the mass of the moon, as well as a number of quantities connected with those already mentioned. In the determination of these constants the plan, as already mentioned, contemplates the utilization and combination of all valuable data.

Besides what is found on the general subject in the present volume the following works are finished or in progress:

LEVERRIER'S tables of the Sun, Mercury, Venus, and Mars have been partially reconstructed with a view of making them more convenient in use. His theory, however, remains unaltered in the manuscript tables. A comparison of the Greenwich, Paris, and Washington meridian observations of Mercury with those tables has been commenced and is approaching completion. Similar comparisons for the Sun, Venus, and Mars have not been seriously commenced, but it is expected to commence them in the course of the year 1883.

A discussion of the corrections required by the older Greenwich observations up to 1830, as published by Professor Airy, in order to reduce the results to a uniform system, is nearly completed, and is expected to appear as Volume II, Part I, of these Papers.

General tables and formulæ for forming the differential coefficients for correcting the elements of the inner planets have been prepared, and it is intended to publish them in the next volume.

Although the final completion of the theories of the other planets must follow the work on the interior planets, it is advisable to begin it without delay, owing to the great labor which it involves. The general perturbations of Jupiter and Saturn were

therefore taken up by Mr. George W. Hill in 1877, but they are still unfinished. It is now expected that Mr. Hill's work will be completed about the end of 1883. The computation has been made principally by the methods of Hansen.

Much attention has also been paid to the subject of the moon's motion. The first object has been the continuance of the discussion of eclipses and occultations previous to 1750 up to the present time. The reason for laying so much stress upon occultations is that notwithstanding the irregularity with which they are observed, their considerable accidental errors, and the labor of reducing them, they constitute the only observations of the moon which are free from systematic error, and which can therefore be used with safety to compare the mean longitudes of the moon at wide intervals of time.

Tabular positions of the moon, as well as those of the fixed stars, are now complete for all the more important occultations since 1750, and the reductions for parallax are in progress. Should the work not be intentionally delayed in order to bring it up to the date at which new tables of the moon shall be actually constructed, it may be expected that this particular discussion will be terminated by the end of 1884.

Although the theory of Jupiter's satellites does not form an essential part of the proposed investigations, the motions of the first satellite are intimately connected with the general subject, owing to the light which they may throw upon the question of the uniformity of the earth's rotation. All the observed and recorded eclipses of the satellites have, therefore, been computed from Damoiseau's tables up to the early part of the present century. The work is discontinued for the present, owing to the difficulty of introducing and discussing the various corrections which will be required to the observations on account of different apertures of telescopes employed, the different distances of the planet from Jupiter, etc. It is a matter of regret to me, as it must be to all astronomers interested in this matter, that Mr. Glasenapp has not continued the very thorough discussion of observations of these satellites which he published some six years ago.

An essential and very laborious and difficult part of the work is that of preparing formulæ and tables for computing the general perturbations of all the planets. A problem which has taxed the powers of the greatest mathematicians of modern times, and the solution of which is still, after all their work, in an unsatisfactory state, is one which the writer feels most hesitation in approaching. He has, however, devised a method which he hopes may prove convenient in practice for the general development of the disturbing function and its derivatives. Whether any improvements can be devised in the method of integrating must be left to the future.

In the future work it is intended to combine the data in a way different from that generally adopted. When all four of the inner planets are considered together it is possible greatly to strengthen the results on special points. An example of this is afforded by the relation of observations on Mercury and Venus to the obliquity of the ecliptic and the position of the equinox. Hitherto these quantities have been made to depend solely upon observations of the sun. Were the sun a point of light which could be observed in the same way as a fixed star, the results from this method would be so far beyond doubt that we should have no occasion to look further. But there are

several causes which diminish the value of solar observations. In the first place, the sun being a round body and not a point of light, it is well known that large personal differences exist in the observations of its position by different observers. Again, it has always to be observed at mid-day, when the atmosphere is most disturbed by its rays, and when the roof of the observing-room is heated from the same cause. Moreover, there is always more or less danger of systematic deformation of the instrument produced by the concentration of the solar rays in the focus. It is therefore impossible to view observations of the sun without a strong suspicion of systematic errors existing among them.

Now, geometrically considered, observations of Mercury may be utilized for determining the position of the earth's orbit relative to the equator almost as well as observations of the sun itself. If we supposed the elements of the orbit of Mercury perfectly known it would be easy to reduce each observation of Mercury to the center of motion. But since the elements of the planet are to be considered unknown, the question arises whether these elements and those of the earth's motion can be independently determined. That they can, to a certain extent, will be evident by the following considerations.

Let us imagine the observer to be in any fixed position on the orbit of the earth, and to observe Mercury from time to time through several revolutions around the sun. It is evident that from these observations the orbit of the planet, and the position of the observer relative to it, could both be determined. By supposing him to move around the earth's orbit to different positions, and to repeat the determinations, we see that any number of separate determinations of the elements of the planet could be made. The several determinations would then be combined and reconciled by attributing suitable elements to his own motion around the earth's orbit.

This is substantially the actual case except that the observations from any one point of the earth's orbit do not embrace the whole orbit of Mercury, but only those portions of it not very near the points of conjunction with the sun. Although this circumstance detracts from the completeness of the determinations it does not detract from the accuracy with which the main problem, that of the obliquity of the ecliptic and position of the equinox, can be solved. It is therefore possible, from meridian observations of Mercury alone, to obtain the principal elements of the earth's orbit around the sun, including the absolute longitude of the sun itself, and hence a separate determination for the position of the equinox. It is true that some of the elements, especially the eccentricity and longitude of the perihelion, may prove to have small weight, but this is because what is most accurately given by the observations will be a linear function of the corrections to these elements. But even such a result will furnish valuable data for the final values of the necessary quantities.

Nearly the same remarks apply to the meridian observations of Venus, and, to a limited extent, to those of Mars. Indeed it is evident that what is given by planetary observations generally is not the absolute position of the planet but the direction of the line joining the earth and planet, which direction is equally available for the determination of the elements of either of the two bodies. Whether it is advisable to employ it in determining both sets of elements must depend upon circumstances. If it

were possible to determine the solar elements by observations of the sun with an accuracy far exceeding the joint determination by observations of the planet, the latter might be entirely omitted. But, for reasons already pointed out, this is far from being the case. It seems better, therefore, under the circumstances, to ascertain what functions of the corrections to the two sets of elements can best be determined from observations of the planets, and to supply whatever is weak in the combination by observations of the sun itself.

In theory, observations of the moon might also be utilized for an absolutely independent determination of the equinox and of the obliquity of the ecliptic. In fact the mean orbit of the moon during a period of one revolution of the node is the ecliptic itself, and therefore exact observations of its position through one period will give the position of the ecliptic. But the rapid motion of the moon in declination when near either equinox introduces a large probable systematic error into the measures made upon it at any definite moment. No weight can therefore properly be assigned to a position of the equinox by meridian observations of the moon. The obliquity derived from such observations may, however, be worthy of more consideration.

The position of the sun among the stars may, however, be determined through the aid of the moon with a considerable approach to precision. The direct comparison of the sun and stars through the sidereal clock is uncertain, from the causes already pointed out, namely, the effect of the sun's rays in disturbing the air and instruments, and personality in observing a limb. Now, by observations of eclipses, especially at the beginning and ending of totality, the exact moment when the sun and moon are in conjunction is determined with great precision. By observations of occultations the mean position of the moon among the stars is determined with yet greater precision. Hence, by a combination of the two we have a result for the position of the sun among the stars which may possibly be entitled to considerable weight. It is, however, a drawback to the method that few observations of eclipses having any claim to precision were made between 1720 and 1800, while those made before 1720 are of course subject to more or less suspicion of systematic error.

It is worthy of note that this method of determining the position of the sun among the stars is, in principle, that adopted by HIPPARCHUS and PTOLEMY.

The above are the leading features in which the plan of the proposed work differs from that hitherto followed. The objects are also somewhat different, in that they include a basis for future conclusions as well as the determination of astronomical constants and the construction of new tables. It is hoped, should the work be completed on the proposed plan, that for a miscellaneous and frequently inconsistent combination of astronomical constants there will be substituted a consistent set, and that the result of this substitution will be to make it easy to determine, from any future deviation between theory and observation which may show itself, in what direction we are to look for the cause.

SIMON NEWCOMB.

ON THE

RECURRENCE OF SOLAR ECLIPSES

WITH

TABLES OF ECLIPSES

FROM B.C. 700 TO A.D. 2300

BY

SIMON NEWCOMB

PREFACE.

The following paper presents a new theory of the recurrence of solar eclipses, founded on some hitherto unnoticed properties of the 18-year eclipse cycle. This theory has been utilized in the formation of tables whereby the solar eclipses of any class which have occurred during the past twenty-five centuries, or are to occur during the next five centuries, may be determined and approximately computed with great rapidity. The tables are founded on the mean motions and other elements of the sun and moon given in Hansen's Tables, the mean motion of the moon and of its nodes being corrected to accord with the results deduced in the author's Researches on the Motion of the Moon.

In the concluding section, the eclipses most remarkable for the duration of total phase are pointed out, and the conditions for their occurrence briefly discussed.

A considerable part of the work of constructing the tables has been performed by Mr. John Meier, assistant in this office.

THE RECURRENCE OF SOLAR ECLIPSES.

≬ 1.

GENERAL THEORY.

It has been known from ancient times that eclipses both of the sun and moon generally repeat themselves in a cycle of 18 years and 11 or 12 days, known as the Saros. This cycle is due to the circumstance that 242 revolutions of the moon relatively to either of its nodes require nearly the same period with 19 revolutions of the sun relatively to the same node. The time required for either of these returns is $6585\frac{1}{3}$ days. Hence, if we note the relative positions of the sun and moon at any moment, and then count forward through this period, we shall, at the end of it, find them in nearly the same position, both relative to each other and relative to the node. If we start from the centre of an eclipse, when the two bodies are nearly in the same straight line, we shall, at the end of the period, find another eclipse very similar in its character. This relation affords a very simple and easily applied method of finding the series of eclipses which occur during any period of 18 years, from those which occurred during the cycle previous

There are, however, two remarkable chance relations connected with the Saros, which, so far as I know, have never been remarked, and without which the period would not have served the purpose of foreseeing eclipses so well as it actually does. The cycle takes account only of the mean motions of the sun and moon. But in consequence of the eccentricity of the orbits, the sun may be 2 degrees on either side of its mean place and the moon 5 degrees. The relative position of the two bodies may therefore vary 7 degrees from their mean position at any time; this extreme variation would change the time of an eclipse by half a day and the distance from the node at which it occurred about 2 degrees. If the corresponding eclipses in two successive cycles were subject to these independent variations, their circumstances might differ so widely that the recurring eclipse would differ considerably from its predecessor, and might be nearly a day later or earlier than the mean length of the cycle in its recurrence. A partial eclipse might fail entirely to recur, and a total one might become partial at the first recurrence and then total again at the second one. But, as a matter of fact, the irregularities of this class are reduced almost to nothing by two other remarkable relations. At the end of a Saros, not only are the sun, the moon, and the node found nearly in their original relation, but the mean anomaly of the moon has also the same value to less than 3 degrees, and the mean anomaly of the sun to some 12 degrees. There is no a priori reason that this should be the case: it arises only from the fact that 18 years is a close multiple, not only of the times of revolution of the sun and moon, but also of the times of revolution of the moon's node and perigee. The following is a more exact statement of the changes at the end of the Saros. Taking as a period the time required for 223 lunations, the changes in the elements at the end of the period will be as follows:—

In the argument of latitude, - - - - - - - - - 28'.6

In the moon's mean anomaly, - - - - - - - - - 2°.831

In the sun's mean anomaly, - - - - - - - + 10°.494

In the distance of the lunar perigee from the node, - + 2°.353

In the distance of the solar perigee from the node, - - 10°.971

In consequence of the minuteness of these changes, not only the mean place of the moon, but all its larger inequalities, will return nearly to their original values at the end of the period. This will hold true, not only with respect to the time of the eclipse, but also with respect to its character, since the parallax and semi-diameter of the moon must also return nearly to their original values. If the eclipse is of a remarkable character with respect to duration, the corresponding ones of succeeding cycles will be of the same character.

An interesting illustration of this fact is found in a series of total eclipses now in progress, namely, those of 1850, 1868, 1886, etc., in which the duration of totality is greater than in any others which have occurred for several centuries. This series will be investigated in the course of the present paper.

Owing to the mean retrocession of 28' from the node in each cycle, the corresponding eclipses in successive cycles are subject to a progressive change. A series of such eclipses commences with a very small eclipse near one pole of the earth. Gradually increasing for about eleven recurrences, it will become central near the same pole. Forty or more central eclipses will then recur, the central line moving slowly toward the other pole. The series will then become partial, and finally cease entirely. The entire duration of the series will be more than a thousand years. A new series commences, on the average, at intervals of thirty years.

It follows from this that all eclipses may be divided into sets, the separate eclipses of each set being separated by intervals of one 18-year cycle, and extending through sixty or seventy cycles. Moreover, from the elements of the central eclipse of each set, those of any other of the same set may be readily found by applying the changes corresponding to the number of intervals which separate it from the central one. It is now proposed to utilize this circumstance by the formation of a series of tables, by which the approximate elements of any solar eclipse between the years B. C. 700 and A. D. 2300 may be found with a few minutes' calculation, and by which any such eclipse occurring during this period may be promptly identified. The principles on which the most important of these tables are constructed may be readily comprehended by a conception of movable conjunction points reached in the following manner.

Let us suppose the mean motions, n and n', of two bodies, planets for instance, revolving round a common centre, to be so related that

$$i' n - i n' = 0$$

i and i' being integers. Then, i' revolutions of the first will require the same period as i revolutions of the second, so that at the end of this period, which we may call P, they will have returned to their original positions. During the period P they will have been in conjunction i-i' times at the same number of equidistant points of either orbit. Every subsequent mean conjunction will occur at these same points. We shall call them *conjunction points*, and shall represent their number, i-i', by ν .

If we suppose these points to be numbered, in the order of longitude, 0, 1, 2 cdots cdots cdot cdots cdots

$$i'x - iy = \pm p$$
.

x will then be the entire number of revolutions of the one planet and y that of the other before the required conjunction will occur; that is, the one planet will then have passed over vx + p intervals between the conjunction points, and the other over vy + p. The condition that these two quantities shall be in the ratio i:i' gives the above indeterminate equation. In order to avoid the ambiguous sign, we may suppose n > n', which will make i > i'. This will make the equation

$$i' x - i y \equiv p$$
.

In what precedes, we have supposed the mean motions of the two bodies to be exactly in the ratio of the entire numbers i and i'. This is never the case in nature, if we reckon the mean longitudes from a fixed point of departure; but we may always assign such a uniform progressive motion to this point that the condition shall be fulfilled. Let us put k for the progressive motion required. The mean motions relative to the moving departure point will then be n-k and n'-k respectively. The condition that these shall be in the ratio i:i', or

$$\frac{n-k}{n'-k}=\frac{i}{i'},$$

gives

$$k \equiv \frac{i \, n' - i' \, n}{i - i'} \equiv \frac{i \, n' - i' \, n}{\nu}.$$

The conjunction points, being fixed relatively to the departure point, will have this same mean motion k; that is:—

By assigning to the ν conjunction points the uniform mean motion k, the conjunctions of the two bodies will always take place at these points.

This conception of movable conjunction points is of great assistance in representing and investigating the relations of the two bodies through many revolutions. For instance, in the case of Jupiter and Saturn, taking $i \equiv 5$ and $i' \equiv 2$, there will be three conjunction points having a direct mean motion of 489" per annum relative to a fixed equinox. Their successive passages through a fixed point occur at intervals of

883 years, and we may consider the great inequality between the two planets as depending on the position of the conjunction points relative to their perihelia.

Theoretically, the values of *i* and *i'* may be regarded as entirely arbitrary. But to obtain the advantage of the conception, we take them as nearly as practicable in the ratio of the mean motions. Even with this limitation we have a choice of systems, an increase in the assumed values of *i* and *i'* having the disadvantage of increasing the number of points to be considered, and the advantage of diminishing their mean motion. The most advantageous systems will of course be found by developing the ratio of the mean motions as a continued fraction, and taking the successive converging fractions which approach to the ratio. Between two such successive systems the following relation subsists:—

The interval between the successive transits of the conjunction points of one system over any one of the next higher, and therefore more slowly moving system, is equal to the time required for the conjunctions to occur at all the points of this latter system.

Commencing with the higher system, and supposing the mean motions n and n' to be counted from a point of this system, and to be in the ratio j:j', we shall have

$$j'n-jn'\equiv 0.$$

The mean motion of the points of the next lower system relatively to the higher one will then be,

$$k \equiv \frac{i \, n' - i' \, n}{i - i'};$$

the time required for a complete revolution of the lower system will be,

$$\frac{2\pi}{k} = \frac{360^{\circ}(i-i')}{i\,n'-i'\,n};$$

and the intervals between successive passages of its i - i' points over a fixed point of the other system will be,

$$\frac{2\pi}{vk} = \frac{360^{\circ}}{i\,n'-i'\,n}.$$

Since n and n' are in the ratio j:j', we may put

$$n \equiv \alpha j,$$

$$n' \equiv \alpha j',$$

which will make

$$i n' - i' n = (i j' - i' j) \alpha$$
.

But, by the properties of continued fractions, the value of the coefficient of α in this expression is ± 1 . Hence, the sign being indifferent, as expressing only the direction of the motion, the interval between successive passages of the conjunction points becomes

$$\frac{360^{\circ}}{\alpha}$$

In order that the conjunctions may occur at all points of the higher system, it is necessary that the one planet should make j and the other j' revolutions. The time required for this will be,

$$\frac{j}{n}360^{\circ} = \frac{j'}{n'}360^{\circ} = \frac{360^{\circ}}{\alpha}$$

the same as the interval just found.

Let us now apply these methods to the problem now under consideration, that of the recurrence of solar eclipses. Let us put

- g, the mean anomaly of the moon;
- g', that of the sun;
- ω , the distance of the lunar perigee from the node;
- ω' , that of the solar perigee from the moon's node;
- T, the number of Julian centuries after 1800.

Applying to the elements given by Hansen (Tables de la Lune, p. 15) the corrections to the mean longitude and the longitude of the node given in my Researches on the Motion of the Moon, p. 268 and p. 274, the numerical expressions for g, ω , g', and ω' will become:—

$$g = 110^{\circ} 19' 32''.50 + (1325^{\circ} + 715807''.98) T + 45''.58 T^{2} + 0''.050 T^{3}$$

 $\omega = 192^{\circ} 7' 21''.91 + (16^{\circ} + 875512''.07) T - 44''.32 T^{2} - 0''.044 T^{3}$
 $g' = 0^{\circ} 24' 28''.22 + (100^{\circ} - 3392''.18) T - 0''.56 T^{2}$
 $\omega' = 246^{\circ} 13' 50''.28 + (5^{\circ} + 489\dot{0}88''.09) T - 6''.52 T^{2} - 0''.007 T^{3}$.
Epoch, + 1800.0, Jan. o, Greenwich mean noon.

In dealing with a subject of this kind, the entire revolution is a more convenient unit than the angular denominations usually adopted. We therefore transform these angles into revolutions and fractions, with the following results:—

$$g = ^{r}.30646026 + 1325^{r}.55232097 T$$

$$+ o^{r}.00003517 T^{2}$$

$$+ o^{r}.00000039 T^{3}$$

$$\omega = ^{r}.53367431 + 16^{r}.67554944 T$$

$$- o^{r}.00003420 T^{2}$$

$$- o^{r}.00000034 T^{3}$$

$$g' = ^{r}.00113289 + 99^{r}.99738258 T$$

$$- o^{r}.00000043 T^{2}$$

$$\omega' = ^{r}.68397398 + 5^{r}.37738278 T$$

$$- o^{r}.00000503 T^{2}$$

$$- o^{r}.000000005 T^{3}.$$

In the construction of the present tables we shall use the Julian calendar, it being more convenient to change the dates from this calendar to the Gregorian than to take account of the complexities of the latter. We shall therefore take, as our fundamental epoch,

1800, Jan. 1, Greenwich mean noon of the Julian calendar, = 1800, Jan. 12, Greenwich mean noon of the Gregorian calendar.

Transferring to this epoch, the constants of the four principal elements will become,

$$g_{\circ} = 0^{r}.74196000,$$

 $\omega_{\circ} = 0^{r}.53915294,$
 $g'_{\circ} = 0^{r}.03398624,$
 $\omega'_{\circ} = 0^{r}.68574068,$

while the coefficients of the powers of T will remain unaltered.

We shall count the time from this epoch in Julian centuries or in equal Julian years of 365.25 days each. This reckoning of time will hereafter be called a fictitious one to distinguish it from the civil reckoning. The expression for the mean distance of the two bodies from the ascending node of the moon's orbit, which we shall represent by u and u', putting

$$u = g + \omega,$$

 $u' = g' + \omega',$

will now be

$$u = 0^{7}.281112.94 + 1342^{7}.227870.41 T + 0.96 T^{2} + 0.005 T^{3},$$

 $u' = 0^{7}.719726.92 + 105^{7}.374765.36 T - 5.46 T^{2} - 0.005 T^{3}.$

The comma in these expressions is used to cut off six places of decimals.

If we differentiate these expressions with respect to T, and then put T = 0 and T = -25, we have the following expressions for the mean motions from the node at the epochs -700.0 and +1800.0:—

Epoch,
$$-700.0$$
, $+1800.0$,

Mean motion of $u = \mu$, $1342^{r}.227832$ $1342^{r}.227870,41$

Mean motion of $u' = \mu'$, $105^{r}.375028$ $105^{r}.374765,36$.

Developing the ratios of these two quantities into a continued fraction, we have,

For -700.0, For + 1800.0,
$$\frac{\mu}{\mu'} = 12 + \frac{1}{1} + \frac{1}{2} + \frac{1}{1} + \frac{1}{4} + \frac{1}{3} + \frac{1}{3} + \frac{1}{7}.$$

The several converging fractions, so far as it is worth while to carry them, are :-

For
$$-700.0$$
: $\frac{12}{1}$, $\frac{13}{1}$, $\frac{38}{3}$, $\frac{51}{4}$, $\frac{242}{19}$, $\frac{777}{61}$, $\frac{2573}{202}$, etc.
For $+1800.0$: $\frac{12}{1}$, $\frac{13}{1}$, $\frac{38}{3}$, $\frac{51}{4}$, $\frac{242}{19}$, $\frac{777}{61}$, $\frac{4127}{324}$, $\frac{4904}{385}$, etc.

Of these systems the one which offers the greatest advantages is $\frac{242}{19}$, which will give us 223 conjunction points, each having (relative to the node) a retrograde motion such that it would, if constant, make a revolution in about 14,000 years. This time, however, varies with the mean motion of the moon and its node. From the formulæ for k, already given, we find,

Epoch,
$$-$$
 700.0: $k = -.0007050$,
Epoch, $+$ 1800.0: $k = -.0007338$.

The distance apart of two consecutive conjunction points is,

$$K = \frac{I^r}{223} = 0^r.004484304 = I^0.614350;$$

and they pass the node at the following intervals:—

At the epoch
$$-$$
 700.0, interval $=$ 63 y .607 $=$ 785 lunations. At the epoch $+$ 1800.0, interval $=$ 61 y .111 $=$ 756 lunations.

Between these two fundamental epochs there will be 40 passages of conjunction points through the node.

We next investigate the positions of the conjunction points at the first of these epochs. We note that a conjunction (new moon) occurred 7^d.01670 before the first epoch, when

$$u = u' = 0^{r}.327024$$

= 73 K - 0^r.000330
= $\left(73 - \frac{1}{14}\right)$ K.

We conclude that the node is very near the 73d conjunction point back from that at which the new moon just found occurred, and that this point passed the node about $\frac{1}{14}$ th of an interval, or $4\frac{1}{2}$ years before the epoch. We shall take this as the zero conjunction point, and count the others in the order of longitude. Their successive passages across the ascending node will then occur at the times shown in the left-hand half of the following table. The intervals between consecutive passages, as just shown, will diminish from $63^{y}.607$ at -700.0 to $61^{y}.111$ at +1800.0.

Passages of Conjunction Points through Nodes.

18	430.01	43	1972.87	130	461.24	155	2003.32
19	492.47	44	2033.77	131	523.67	156	2064.19
20	554.87	45	2094.61	132	- 586.04	157	2125.00
21	617.21	46	2155.39	133	648.34	158	2185.75
22	679.48	47	2216.11	134	710.59	159	2246.42
23	741.69	48	2276.77	135	772.76	160	2307.03
24	803.84	49	2337.37	136	834.88	161	2367.58

At the first of the above epochs the descending node will fall between the IIIth and the II2th conjunction point, and the passages will occur midway between those of the ascending node. These times are shown in the right-hand portion of the table.

A new moon occurs at each conjunction point at equal intervals of 223 lunations; and, according to the system adopted, eclipses are classified according to the conjunction point at which they occur, those of each series being separated by intervals of 223 lunations. The middle eclipse of each series will be that which occurs nearest the time when the conjunction passes the node; and we now wish to find when these successive middle eclipses occur. We have just seen that the sun and moon were together at the 73d conjunction point on the 7th day before — 700.0. We wish to find when they were together at the zero point, which is 150 points farther advanced. Each new moon occurs at an interval of 19 conjunction points past the preceding one; therefore, if be the number of lunations required, we must have

This gives:—
$$i \equiv 150 \pmod{223}$$
.
 $i \equiv 137$, or $i = -86$.

The required conjunctions at the zero point are therefore the 137th following and the 86th preceding that of -700° -7° , from which we started. The latter, of course, is nearest the node.

The number of lunations between a conjunction at any point and the first following conjunction at the next point in order is given by the congruence,

$$19 i \equiv 1 \pmod{232}$$

the solution of which is,

$$i = 47.$$

We shall therefore have a conjunction at point n + 1 at an interval of 47 lunations after any conjunction at point n, whatever be n. The intervals between consecutive middle eclipses must therefore be of the form,

$$223 x + 47,$$

x being an integer. The mean interval must be the same as that between two passages of the node over a conjunction point; that is, 785 lunations about the epoch - 700.0 and 756 lunations about the epoch + 1800.0. The actual intervals are there fore found by putting x = 3 and x = 4, so that they must be either

716 or 939 lunations.

§ 2.

DATA FOR TABLES OF ECLIPSES.

When the possible solar eclipses which may have occurred during any period are to be investigated, it is convenient to have tables by which we can at once find the limits of time within which their occurrence is possible. A central eclipse can occur only within eleven or twelve days of the time when the sun passes the moon's node, and therefore only at the new moon nearest such passage. A partial eclipse may occur at any time within eighteen days of such passage: there may, therefore, be two partial eclipses; one at the new moon preceding, and the other at the new moon following, the passage of the sun through the node. Our first problem is, therefore, to find the dates of passage of the sun through the nodes of the moon's orbit, which gives us at once the middle of what we may call an eclipse season. This is effected by two tables, of which the first gives the dates at which the ascending node has the same longitude that the sun has at the beginning of the fictitious Julian year, and the second the changes in the times of passage for the 19 years following these dates.

The data for the construction of the first table are as follows. Hansen's longitude of the node, corrected, is,

$$\theta = 33^{\circ}$$
 16' 31".15 — 6962929".61 T + 8".19 T² + 0".007 T³,
Epoch, + 1800.0, Gregorian calendar.

Reduced to the Julian epoch, 12 days later, it becomes approximately,

$$\theta = 32^{\circ} 38'.47 - 116048'.827 T + 0'.136 T^{2}$$

The sun's mean longitude at the beginning of the fictitious Julian year is,

291° 44′ + 46′.13 T + 0′.021
$$T^2$$
.

The distance of the node from the chosen departure point is,

$$100^{\circ}$$
 54' — 116094'.96 T + 0'.116 T².

The annual motion and period are,

Epoch,
$$-$$
 700.0, $m = -$ 116100'.76; Period $=$ 18^y.60453: Epoch, $+$ 1800.0, $m = -$ 116094'.96; Period $=$ 18^y.60546.

The first passage through the departure point after + 1800.0 is at the epoch

The 135th passage preceding is at the epoch

Table II gives the days of the fictitious year at which conjunctions of the mean sun with either node occur. The argument is the interval which must elapse after the beginning of the year under examination before the next following conjunction in Table I. The units of the argument are on the left hand, and the tenths on the top of the table. Eclipses can occur only near one of the two or three epochs found in this table, unless a conjunction has occurred near the end of the year preceding or shortly after the beginning of the year following.

Table III, on the same page, gives the reduction from the time of mean to that of true conjunction of the sun with the node, which reduction arises from the eccentricity of the earth's orbit. This table is used only to make more definite the eclipse limits by enabling us to decide whether an eclipse could or could not occur at a given conjunction in cases where the mean values of the argument might leave the question doubtful.

Table IV enables us to find the moon's mean age at any fictitious Julian date. To the fictitious day of the year we add the value of D corresponding to the century, and that corresponding to the year, and subtract the greatest multiple of Period. We may also subtract the next greatest multiple, and thus obtain a negative value of D, counted backward from the next following conjunction.

By taking, for the required date, that of conjunction of the mean or true sun with the node, we are enabled to judge whether an eclipse of given character could or could not have occurred at the preceding or following new moon.

Tables V and VI give the approximate arguments for the central eclipse of each series from —.700.0 to + 2300.0, a period of thirty centuries. To understand its construction we call to mind that, on the system adopted, the moon's orbit is conceived as divided into 223 equal parts by that number of conjunction points; that this whole system of points has a very slow retrograde motion relative to the moon's nodes, such that 61 years elapse between the passages of two consecutive points; that all mean new moons occur at some one of these 223 points; that those at any one point are separated by intervals of 223 lunations, or one Saros or cycle; that if we isolate every 47th lunation, we shall find these isolated lunations to occur at consecutive conjunction points in the order of longitude.

When a conjunction point, by the slow motion already described, approaches within about 18° of the node, there will be an eclipse of the sun at every new moon which occurs at that conjunction point. The series of eclipses will become central within 10° or 12° of the node, and will continue unbroken until the conjunction point has got 18° beyond the node. We shall thus have a series of central eclipses, generally between 45 and 50 in number, with about 15 partial eclipses on each side of it. The total number will generally range between 75 and 80. Since the conjunction point moves about 0°.48 between the consecutive eclipses of each series, some one eclipse must occur within 0°.24 of the node. This nearest eclipse we have sought to take as the central eclipse of the series; but, in some cases, that chosen is not absolutely the nearest. The numbers in Tables V and VI correspond to the eclipse of each series chosen as the central one.

The intervals between the passages of consecutive conjunction points through the node are about 61 years at the present time, and were 63.6 years 25 centuries ago. This must be the mean interval between consecutive central eclipses. But it has been shown that this interval, expressed in lunations, is necessarily of the form 223 x + 47, x being an integer, and must be either 716 or 939 lunations, the former being the more frequent value.

From the mean motions already given we derive the following numbers and periods for the two fundamental epochs, — 700.0 and + 1800.0, which have served as the basis of Tables V and VI.

	Epoch, — 700.0;	+ 1800.0.
One mean lunation, in days,	29.53059562	29.53058844
Length of Saros, in Julian years,	18.02963127	18.02962689
Length of Saros, in days,	6585.322823	6585.321222
Annual motion of mean anomaly, in rev., -	13.25550638	13 25552321
Motion of mean anom. in one Saros, in rev., -	238.9918923	238.9921377
Change of the same, in degrees,	- 2.9188	- 2.8304
Centennial motion of conj. points, in rev., -	- .0.007050	- 0.007338
Centennial motion of conj. points, in degrees,	- 2.5380	- 2.6417
Motion of conj. points in one Saros, in degrees,	0.45758	— 0.47628
Motion of O's mean anomaly in one Saros, in		
· degrees,	+ 10.4980	+ 10.4947
Motion of ⊙'s mean long. in one Saros, in deg.,	+ 10.8025	+ 10.8037
A R3		

The necessary explanation of the principal columns in Tables V and VI will next be given. The conjunction point at which the new moon of — 689, January 20th, occurred, is arbitrarily taken as the zero one. The others are counted from it in the order of longitude. The slow retrograde motion of the whole system relatively to the node causes them to cross the node in the same order.

In column T is found the fictitious Julian date of the central eclipse of each series, already described. Any one of these dates being found, the next following is derived by adding to it the time either of 716 or 939 lunations; such intervals being chosen as would keep the dates near the times of passages of the corresponding conjunction point through the node. A table of these passages has already been given. Near the beginning and end of the table, the regular order has been deviated from, for the reason that it was supposed that there would be no occasion to use the tables for epochs outside the limiting dates, — 700.0 and + 2300.0, while it was desirable to be able to compute all the partial or total eclipses within these dates. Many of these eclipses would, however, take place at conjunction points the central eclipse of which might take place several centuries without the limits. Instead of choosing the central eclipse of the series, one occurring near the limiting epoch was chosen in each case.

It may also be noted that the years before Christ are reckoned in the usual astronomical way; the year immediately preceding the first of the Christian era being considered as zero, the next preceding being — 1, etc. The days are, however, considered as positive; so that if we express any one of these dates in years and fractions, the integer number of years would be one less than in the table.

The reckoning of fictitious time throughout the table is that already explained, namely, taking Greenwich mean noon of 1800, January 12th, as the epoch, we call this epoch 1800.0, and count backward and forward by years of $365\frac{1}{4}$ days each. The days are, therefore, not always reckoned from noon, but from noon, 6 hours, 12 hours, or 18 hours, according to the number of the year. A correction is therefore required to reduce to the time of noon, and, since 1582, a still further correction to reduce from the Julian to the Gregorian calendar. These corrections are shown in Table XIII b.

The times of mean conjunction correspond to Hansen's mean motion and secular variation, with the corrections given in my Researches on the Motion of the Moon, page 268,* the periodic terms being omitted.

The times of mean conjunction, as given, are generally accurate to one or two units in the last place of decimals, or to 8" or 10" of arc in the relative positions of the sun and moon. Their errors, therefore, fall far within the necessary uncertainty of the lunar theory in past and future centuries.

The moon's mean anomaly, g, has been divided from -180° to $+180^{\circ}$, for greater convenience in the selection of total eclipses. It is derived from Hansen's tables, applying the same correction as to the mean longitudes.

The sun's mean anomaly, g', and the mean longitude, L, do not seem to require any special explanation.

The moon's mean argument of the latitude, u_o , has been derived from the difference between the date of each central eclipse and the passage of the conjunction point

^{*} Washington Observations for 1875, Appendix II.

through the node, and is equal to the motion of the conjunction points during this interval.

Table VI, which gives the mean elements for eclipses at the descending node, is constructed on the same principles. Here the argument of latitude, $u_o - 180^\circ$, is of course counted from the descending node.

Table VII gives the reduction of the arguments in Tables V and VI for other eclipses of the same series. In the use of the tables for calculating a particular eclipse, it is necessary to find the date of the central eclipse of the series to which the one under consideration belongs, as given in Tables V and VI. This is readily done by the precepts given in the tables. Having found the central eclipse, the elements for the required eclipse are deduced by adding the corrections for the number of periods elapsed, as given in Table VII. Owing to the secular changes in the motion of the arguments, these motions are given for three epochs, namely, the year 0, the year 1000, and the year 2000 of our era. For greater facility in the use of the tables, the change in the last place of decimals for intervening centuries is added wherever it is necessary. In using these tables, the number must be taken out for an epoch midway between that of the central eclipse and that of the eclipse to be computed.

Having found the arguments for the moment of mean conjunction, the next step is to deduce the elements for the moment of true conjunction. The theory of this process has been fully developed by Hansen in his Analyse der ecliptischen Tafeln.* The same author has given tables for the approximate computation of eclipse elements, which are of direct application to the problem as here presented. These tables are, however, rather meagre, and can only be used in connection with the author's tables of the moon. On the other hand, the formulæ in the later paper are developed with such fullness that it is not necessary to go over them. I shall, therefore, accept Hansen's results, with such modifications as are necessary to make them applicable to the form of tables now proposed. The following are the modified expressions.

A general remark, applicable to the tables, is, that the quantities required are given for the moment of true conjunction in ecliptic longitude, but are expressed in terms of the values of g, g', etc., at the moment of mean conjunction.

(1) Reduction from time of mean conjunction to that of true ecliptic conjunction.

$$\delta T = -o^{d}.4089 \sin g$$

$$+ o^{d}.0161 \sin 2 g$$

$$- o^{d}.0004 \sin 3 g$$

$$+ o^{d}.1743 \sin g'$$

$$+ o^{d}.0021 \sin 2 g'$$

$$- o^{d}.0051 \sin (g + g')$$

$$+ o^{d}.0075 \sin (g - g')$$

$$+ o^{d}.0104 \sin 2 u.$$

(2) True argument of latitude, reduced to the ecliptic, for the moment of true conjunction.

In the special form of tables adopted, it is necessary to reduce the mean longitudes of the two bodies at the moment of mean conjunction to their true longitudes at the

^{*} Berichte über die Verhandlungen der Königlich-Sächsischen Gesellschaft der Wissenschaften, Bd. XV, Leipzig, 1863, and Bd. IX, 1857.

moment of true conjunction. If the expression for the elapsed time between mean and true conjunction is correct, this reduction ought to be the same for both bodies. Hansen gives its expression for the moon; the corresponding correction for the sun is,

Mean motion during interval + Equation of centre for true conjunction.

Putting δT for the elapsed interval, and g', for the mean anomaly at the moment of true conjunction, the required reduction will be,

$$n'\delta T + 1^{\circ}.922 \sin g'_1 + 0^{\circ}.020 \sin 2g'_1$$

where we must put

$$g' = g' + n' \delta T$$
.

Substituting this value, and developing, the expression will be,

$$n'\delta T (1 + 0.0335 \cos g') + 1^{\circ}.922 \sin g' + 0^{\circ}.020 \sin 2g'$$
.

Substituting the value of $n\delta T$ just given, we find the following expression for the true ecliptic distance of both bodies, counted from the node, at the moment of true conjunction, u being the mean distance at the moment of mean conjunction:—

$$u_1 = u - 0^{\circ}.403 \sin g$$

$$+ 0^{\circ}.016 \sin 2g$$

$$+ 2^{\circ}.094 \sin g'$$

$$+ 0^{\circ}.027 \sin 2g'$$

$$+ 0^{\circ}.012 \sin (g+g')$$

$$+ 0^{\circ}.010 \sin 2u$$

$$= u - .00703 \sin g$$

$$+ .00028 \sin 2g$$

$$+ .00047 \sin 2g'$$

$$- .00021 \sin (g+g')$$

$$+ .00017 \sin 2u.$$

(3) Vertical distance of the axis of the moon's shadow from the centre of the earth at. the moment of ecliptic conjunction.

The expression for this element is,

$$y_2 = \frac{\sin \int s \, \text{latitude}}{\sin (\pi - \pi')}$$
.

Hansen puts it into the form,

$$B = P \cos u + Q \sin u = y_s$$

Its numerical expression will, however, be a little more simple by substituting u_i , the true argument of latitude, for u, the mean argument. Hansen's expressions for P and Q are nearly as follows, some very small terms being omitted:—

$$P = -.0392 \sin g$$

$$+.0116 \sin 2g$$

$$+.2080 \sin g'$$

$$+.0024 \sin 2g'$$

$$-.0073 \sin (g+g')$$

$$+.0067 \sin (g-g')$$

$$+.0118 \sin 2u$$

$$Q = + 5.2207$$

$$-0.3299 \cos g$$

$$+0.0020 \cos g'$$

$$+0.0020 \cos 2g'$$

$$-0.0060 \cos (g+g')$$

$$+0.0041 \cos (g-g')$$

If we suppose

$$y_z = P_x \cos u_x + Q_x \sin u_x$$

we shall have,

$$P_{r} \equiv P \cos (u_{r} - u) - Q \sin (u_{r} - u),$$

 $Q_{r} \equiv Q \cos (u_{r} - u) + P \sin (u_{r} - u).$

From the preceding expression for u, we find,

$$\cos (u_1 - u) = 1 - .00036$$
 $- .00034 \cos 2 g'$
 $+ .00014 \cos (g + g')$
 $- .00014 \cos (g - g')$

while we may suppose

$$\sin(u_1-u)\equiv u_1-u$$
.

We then find,

$$Q \sin (u_1 - u) = -0386 \sin g \qquad Q \cos (u_1 - u) = Q - .0019 + .0025 \sin 2 g \qquad - .0018 \cos 2 g' + .1917 \sin g' \qquad + .0007 \cos (g + g') + .0022 \sin 2 g' \qquad - .0007 \cos (g - g'). - .0070 \sin (g + g') + .0060 \sin (g - g').$$

$$P \sin (u_{1} - u) = +.0039 \qquad P \cos (u_{1} - u) = P.$$

$$-.0002 \cos 2 g$$

$$-.0038 \cos 2 g'$$

$$+.0014 \cos (g + g')$$

$$-.0014 \cos (g - g').$$

$$P_{1} = -.0006 \sin g \qquad Q_{1} = +5.2227$$

$$+.0091 \sin 2 g \qquad -0.3299 \cos g$$

$$+.0163 \sin g' \qquad -0.0048 \cos g'$$

$$+.0002 \sin 2 g' \qquad -0.0036 \cos 2 g'$$

$$-.0003 \sin (g + g') \qquad -0.0039 \cos (g + g')$$

$$+.0007 \sin (g - g') \qquad +0.0020 \cos (g - g').$$

$$+.0118 \sin 2 u.$$

The value of P_i is so small that we may suppose $\cos u_i = \pm 1$ in multiplying it by this quantity. In a total eclipse, the value of u_i can differ from 0° or 180° by only about 11° , and that of u by only about 16° . We shall, therefore, obtain a result nearly accurate to the third place of decimals by replacing $0.0118 \sin 2 u$ by $0.022 \sin u_i$. A sufficiently accurate expression for y_i will therefore be,

$$y_z = P_x + Q_x \sin u_x;$$

or, omitting terms which will not change y_2 by .001,

$$y_2 = \pm (-.0006 \sin g + .0091 \sin 2g + .0163 \sin g') + (5.245 - 0.330 \cos g) \sin u_1$$

the upper sign being used at the ascending and the lower at the descending node. An error of a unit in the third place of decimals corresponds to one of about 5' in the position of the shadow-path on the earth's surface; the probable error of the shadow-path, on account of the quantities neglected in y_2 , will therefore not exceed 10 or 15 miles.

(4) For the hourly motion of the axis of the shadow along the fundamental plane,*
Hansen's expression is equivalent to

$$x'_{2} = \frac{dx_{2}}{dt} = + 0.5410 \qquad y'_{2} = \frac{dy_{2}}{dt} = (.0540 + .0034 \cos g) \cos u_{1}.$$

$$+ 0.0397 \cos g$$

$$- 0.0010 \cos g'$$

$$+ 0.0006 \cos (g + g')$$

$$- 0.0004 \cos (g - g').$$

We may, without an error exceeding 0.001, regard $\frac{dy_2}{dt}$ as equal to $\frac{1}{10} \cdot \frac{dx_2}{dt}$.

(5) The radius of the shadow on the fundamental plane and the angle of the shadow-cone are given by the formulæ,

$$\rho = +0.0059 \qquad \sin f = +0.004653 +0.00078 \cos g' +0.0005 \cos (g+g').$$

When ρ is positive, the eclipse will be annular; when negative, total.

The value of ρ for external contact may be found by increasing the above by 0.5460, which will make the constant term 0.5519. The same value of sin f may be used in the two cases.

Circumstances of an Eclipse on the Earth's Surface.—Our next step is to find the relation of any point on the earth's surface to the shadow. Several systems of co-ordinates may be adopted for this purpose, which vary with the adopted direction of the axis of X on the fundamental plane. We have the choice of three systems, depending on the following three positions of this axis of X in the fundamental plane:—

- (1) The intersection of the earth's equator with the fundamental plane;
- (2) The intersection of the ecliptic with the same plane;
- (3) A line in the same plane parallel to the path of the axis of the shadow along it. The first system is that of Bessel, while the second and third have been used by Hansen.

^{*}It will be remembered that the fundamental plane in the theory of eclipses passes through the centre of the earth perpendicular to the axis of the shadow.

Let us put

- O, the sun's true longitude, or, more exactly, the longitude of the sun as seen from the moon;
- ε, the obliquity of the ecliptic;
- a, d, the right ascension and declination of the sun as seen from the moon, for which, in the present case, we may take the geocentric direction of the sun;
- α , the angle of the shadow-path along the fundamental plane with the intersection of the ecliptic with the same plane;

 $h = \rho \cos \varphi'$ ρ being here the earth's radius and φ' the geocentric latitude $k = \rho \sin \varphi'$ of any point on its surface.

For the present we shall represent the co-ordinates corresponding to these various systems by subscript numbers. It will be remarked that in all the systems the axis of Z passes through the centre of the earth parallel to the line joining the centres of the moon and sun.

The value of the equation of the centre by which \odot is found may be obtained from Table XXVI. The expression is, $\odot = L + \text{Equation}$ of centre.

For the relations between systems (1) and (2), we determine the angle p from any or all of the equations,

$$\cos d \sin p \equiv \sin \epsilon \cos \odot$$
,
 $\cos d \cos p \equiv \cos \epsilon$,
 $\sin d \equiv \sin \epsilon \sin \odot$.

The required relations will then be,

$$x_z \equiv x_1 \cos p + y_2 \sin p,$$

 $y_z \equiv -x_1 \sin p + y_2 \cos p,$
 $z_z \equiv z_1;$

or, reversing them,

$$x_1 \equiv x_2 \cos p - y_2 \sin p$$
,
 $y_1 \equiv x_2 \sin p + y_2 \cos p$.

For the use of the third system, it will be sufficiently accurate to suppose that the axis of x_3 makes an angle of 5° 30' with that of x_2 . With a little greater probable accuracy we may determine the angle α by the condition, $\alpha = \pm 5^{\circ}$.7 cos u_1 , this angle being positive at the ascending and negative at the descending node. Then, putting

$$p' = p + \alpha$$

we shall have,

$$x_3 \equiv x_1 \cos p' + y_1 \sin p' \equiv x_2 \cos \alpha + y_2 \sin \alpha,$$

 $y_3 \equiv -x_1 \sin p' + y_1 \cos p' \equiv -x_2 \sin \alpha + y_2 \cos \alpha.$

Tables XVIII to XX give the value of y_2 for the shadow-axis at the moment of conjunction in longitude, when $x_2 = 0$; and Tables XXI and XXII give the hourly

variation of x_2 , from which that of y_2 may be obtained by multiplying by $\tan \alpha$ or by $\cos u_1 \tan (5^{\circ} 42')$. The expressions for x_2 and y_2 will therefore be,

$$x_1 \equiv x'_2 t$$
,
 $y_2 \equiv y^\circ + x'_2 t \tan \alpha \equiv y_2^\circ + y'_2 t$.

Here t is the time after true conjunction, T, expressed in hours as the unit.

To refer the shadow-axis to either of the other systems, we shall then have,

$$x_3 \equiv y_2^{\circ} \sin \alpha + x' t \sec \alpha,$$

$$y_3 \equiv y_2^{\circ} \cos \alpha,$$

$$x_1 \equiv -y_2^{\circ} \sin p + x'_2 t (\cos p - \tan \alpha \sin p),$$

$$\equiv -y_2^{\circ} \sin p + x'_2 t \sec \alpha \cos (p + \alpha),$$

$$y_1 \equiv y_2^{\circ} \cos p + x'_2 t (\sin p + \tan \alpha \cos p),$$

$$\equiv y_2^{\circ} \cos p + x'_2 t \sec \alpha \sin (p + \alpha).$$

The values of the coefficients for x_i and y_i may be taken from Table XXVIII, where we have put

$$a \equiv -\sin p,$$

 $a' \equiv \cos p,$
 $b \equiv \sec \alpha \cos (p \pm \alpha),$
 $b' \equiv \sec \alpha \sin (p \pm \alpha);$

so that the expressions for x_i and y_i are,

$$x_1 = a \ y_2^{\circ} + b \ x'_2 t,$$

 $y_1 = a' \ y_2^{\circ} + b' \ x'_2 t.$

We now require the corresponding co-ordinates for the point on the earth's surface, expressed by the quantities h and k. If we represent these by ξ , η , and ξ , Bessel's eclipse formulæ give,

$$\xi_1 \equiv h \sin H,$$

 $\eta_1 \equiv k \cos d - h \sin d \cos H,$

H being the hour-angle of the sun, or, to speak more exactly, the hour-angle of that point of the sphere representing the direction of the sun as seen from the moon. The other co-ordinates of the place will then be,

$$\mathcal{E}_{2} \equiv k \cos d \sin p + h (\cos p \sin H - \sin d \sin p \cos H),$$

 $\eta_{2} \equiv k \cos d \cos p - h (\sin p \sin H + \sin d \cos p \cos H),$
 $\mathcal{E}_{3} \equiv k \cos d \sin p' + h (\cos p' \sin H - \sin d \sin p' \cos H),$
 $\eta_{3} \equiv k \cos d \cos p' - h (\sin p' \sin H + \sin d \cos p' \cos H).$

The angle H is expressed in terms of t, as follows:—From the conjunction tables V-VII we have, by the corrections from Tables VIII-XII and by correcting for the fictitious date, the fraction of a day of Greenwich mean time at the moment of true

ecliptic conjunction. Multiplying this fraction by 360° (Table XIV), we have the hourangle of the mean sun for the meridian of Greenwich at the moment of conjunction.

Let us put

Ho, this hour-angle;

λ, the longitude of the place west from Greenwich;

E, the equation of time, to be *added* to apparent time in order to obtain mean time, expressed in arc.

Then, at conjunction, the hour-angle of the mean sun will be $H_o - \lambda$, and that of the apparent sun will be $H_o - \lambda - E$. The expression for H, as a function of t, will then be

$$H = H_{\circ} - \lambda - E + 15^{\circ} \times t$$
.

We have now all the data for proceeding with the computation of the eclipse in any of the usual ways.

The data of the present tables are of such accuracy that we may generally expect to predict the phases of an eclipse, by means of them, within one or two minutes of time, and to determine the shadow-path in total or annular eclipses to coarse fractions of a degree. In fact, supposing the tables perfect to the last place of decimals, the probable error of this path should not exceed two or three tenths of a degree, unless near the north or south pole of the earth; but small errors of theory are possible, leading to larger errors in the shadow-path.

The following are the formulæ for the computation of the path of a central eclipse. They are applied by computing the longitude and latitude of the point in which the axis of the shadow intersects the earth's surface at any assumed moment of Greenwich mean time.

Compute the values of x_i and y_i for the assumed moment. Table XXVIII is designed to facilitate this computation.

If it is desired to take into account the ellipticity of the earth, the neglect of which will introduce a probable error of perhaps 10' in the point required (which amount, however, is hardly greater than the necessary uncertainty of the results from the preceding tables), we compute ρ_r and d_r from the formulæ,

$$\rho_{1} \sin d_{1} = \sin d,$$

$$\rho_{1} \cos d_{1} = \sqrt{1 - e^{2}} \cos d = [9.99855] \cos d,$$

$$y'_{1} = \frac{y_{1}}{\rho_{1}}.$$

The values of ρ_1 and d_2 may be taken at once from Table XXIX with the argument $\bigcirc = L + \text{Equation}$ of centre. If, however, we neglect the ellipticity, we put d for d_1 , y_1 for y'_1 , and φ for φ_1 in the following formulæ, which are a continuation of the preceding ones.

From

$$c \sin C = y'_{i},$$

$$c \cos C = \sqrt{1 - x_{i}^{2} - y'_{i}^{2}},$$

find c and C. The last quantity may be computed by the auxiliary angle β , thus:—

$$\sin \beta \sin \gamma \equiv x_i$$
,
 $\sin \beta \cos \gamma \equiv y'_i$,
 $c \cos C \equiv \cos \beta$.

Then, from the equations,

$$\cos \varphi_i \sin H \equiv x_i,$$

 $\cos \varphi_i \cos H \equiv c \cos (C + d_i),$
 $\sin \varphi_i \equiv c \sin (C + d_i),$
 $\tan \varphi \equiv [0.00145] \tan \varphi_i,$

find φ and H. The former will be the latitude of the point required, and the latter the local hour-angle of the shadow-axis. The Greenwich hour-angle is found by the formula,

$$H_1 \equiv H_0 - E + 15^{\circ} t$$
;

H_o being the Greenwich mean time of true conjunction in longitude, expressed in arc; E, the equation of time (Tables XXVI and XXVII); t, the interval of the assumed time after that of true conjunction, expressed in hours The west longitude of the point sought will then be:—

$$\lambda = H_1 - H_2$$

§ 3.

RECURRENCE OF REMARKABLE ECLIPSES.

The occurrence of eclipses approaching the maximum length of totality is a subject of astronomical interest. We have already shown that the successive eclipses at the same conjunction point, occurring at intervals of 18 years, are nearly of the same character. Consequently, if we have at any time an eclipse in which the duration of totality approaches the maximum, we shall have a similar one after a lapse of one period, and the duration will vary but slowly from period to period. We shall therefore search in our tables, not for single eclipses with long duration of totality, but for series of such eclipses, the distinctive mark of each series being the conjunction point at which it occurs.

The conditions necessary to the greatest duration of totality, considered individually, are the following:—

- I. The moon must be near its perigee at the time of conjunction. In other words, its mean anomaly, positive or negative, must be small in absolute value.
- II. The sun must be near its apogee in order that its semi-diameter may be small; hence its mean anomaly must differ little from 180°. It is, however, to be remarked that a deviation of the sun's mean anomaly from 180° will produce only about one fourth the effect of an equal deviation of the moon's anomaly from 0°.

III. The preceding two conditions give the maximum breadth of shadow on the fundamental plane, passing through the centre of the earth at right angles to the axis of the shadow. But, the shadow being conical, its diameter increases as we approach the moon. The observer should therefore be as near the moon as possible. In other words, at the moment of central eclipse, the sun and moon should be near his zenith. The diameter of the shadow at his station will then be nearly one third greater than on the fundamental plane. In order that these conditions may be fulfilled, it is necessary that the observer should be within the tropics and that the conjunction should take place near the node. For, the two bodies being in the zenith, the effect of parallax is zero, and the eclipse must be central at the centre of the earth, which can only occur when the conjunction coincides with the node. These conditions will be most nearly fulfilled by the central eclipses, the dates of which are given in Tables V and VI.

IV. The diurnal motion of the observer must be as great as possible, because by this motion he is carried along in the same direction with the axis of the shadow, and thus the time which he remains within it is increased. This condition is best fulfilled when he is upon the equator.

V. The direction in which the observer is carried by the diurnal motion must be parallel to the direction of the shadow. This condition demands that the direction of the axis of the shadow shall be near the great circle joining the pole of the earth and the pole of the moon's orbit. This condition can be fulfilled only when the sun's longitude is near 90° or 270°; in other words, near the times of the two solstices.

It is impossible that all the preceding conditions can be simultaneously fulfilled, owing to the obliquity of the ecliptic. The 4th condition can be fulfilled only at the equinoxes, and the 5th only at the solstices. Also, since the sun's apogee has, during each century, a nearly definite longitude (at present about 90°), it is only near 90° of the sun's longitude that the 2d condition can at present be fulfilled. In former ages, the case was somewhat different. But the distance of the epoch from these solstices was only about 20° at the beginning of the Christian era. We may see, therefore, that during historic times, and for several centuries to come, the solar eclipses of greatest duration can occur only near the summer solstice. If the eclipse at this time occurs also exactly at the node it will be central in the zenith of the Tropic of Can-Conditions 3d and 5th will therefore be fulfilled, but condition 4th will not. If the latitude of the moon be north at the moment of conjunction, conditions 3d and 4th will both be less favorable. If the latitude be south, condition 4th may be more favorable, because the shadow will then be thrown further towards the equator, but condition 3d will be less favorable. Condition 4th will be best fulfilled by south latitude of about 24', or by an argument of latitude of -4° or -5° near the ascending node and +4° or +5° near the descending node. Beyond these points of latitude, both conditions are unfavorable. We conclude, therefore, that when the two first conditions are properly fulfilled, the most favorable eclipses will be the ten or twelve which follow the central one of each series at the ascending node and the ten or twelve which precede it at the descending node. The most favorable will generally fall between the fourth and the seventh from the central eclipse; and the first two conditions require

that we should then have g = 0 and g' = 0. In order that these conditions should be fulfilled at the sixth eclipse, we should have, near the time of central eclipse, the following system of values of g, g', and L :=

Ascending Node.	Descending Node.
$g = 17^{\circ}$	$g = - 17^{\circ}$
g' \equiv 120 $^{\circ}$	<i>g</i> ′= 240°
$L = 25^{\circ}$	$L = 155^{\circ}$

An examination of Table V will now enable us to select series of remarkable total eclipses almost by inspection. We see that the moon's mean anomaly is repeated within 12° or 15° at every third conjunction point. Considering, first, eclipses at the ascending node, we perceive that the moon's mean anomaly is small at the 10th, 13th, 15th, etc., conjunction points, and that the condition, $g = 17^{\circ}$, is most nearly fulfilled at the 16th and 19th points. The conditions, $g' = 120^{\circ}$ and $L = 25^{\circ}$, though not fulfilled at either point, are so near fulfillment that there were then two series of total eclipses nearer the maximum duration than any which occurred for several subsequent centuries. The last of the most favorable series were in the years 663, 681, 699, etc.

To find other series approaching the maximum of totality, we have to pass over more than a thousand years, until the 42d and 45th conjunction points approach the node. To the 42d conjunction point belong the series of great eclipses of 1832, 1850, 1868, 1886, etc., of which the maximum was that of 1832 or 1850. The position of the solar perigee is unfavorable at this point; otherwise the duration would have gone on increasing through the next century. But at the 45th conjunction point, the conditions are more nearly fulfilled than they have been for at least twenty centuries, and we shall therefore have a series of eclipses approaching within a very few seconds of the maximum duration of totality. These will occur in the years 2150, 2168, etc.

Passing now to the descending node, we see that in a general way the series occur in the same order. The favorable conjunction points near the present epoch seem to be the 149th, 152d, 155th, etc. In the first two of these, the sun's mean anomaly is not favorable except when the moon's is unfavorable. The conditions are better fulfilled at the 155th conjuction point, the central eclipse of which takes place in the year 2009. The eclipses of maximum duration will occur two or three periods before the central eclipse, namely, in the years 1955 and 1973. To this series belong the total eclipses of 1865, 1883, etc. The successive eclipses of this series will therefore increase in duration for five or six periods to come, when the duration will probably be greater than that of any that have preceded them during the past thousand years.

TABLES OF SOLAR ECLIPSES.

TABLE I.

The use of this and the next table is as follows:—Subtract the number of the year, neglecting fractions, from the next larger number (algebraically) in the table. With the excess enter Table II, the entire number being on the side and the tenths at the top. The corresponding number will be the day and tenths of a day of the fictitious Julian year at which the mean sun was in conjunction with the node indicated in the second column. Should the number be negative it will indicate days before the beginning of the year, and should it exceed 365.25 it will indicate a conjunction after the end of the year.

In general, a central eclipse of the sun can only occur within ten or twelve days of the times thus found, and a partial eclipse within eighteen or twenty days. It is to be remarked, however, that an eclipse may occur when the corresponding conjunction takes place near the end of the year preceding, or during the first seventeen days of the year following.

TABLE II.—Days of the Fictitious Year when the Mean Sun is in Conjunction with either Node.

2300	19.9	24	0.0	49	6.3	74	12.6	99	18.9	1	

The age (D) of the mean moon at any time is found by taking the sum of the values of D corresponding to the century and to the year of the century, adding the fictitious Julian date and subtracting the greatest multiple of the period. Generally it will be better to subtract the multiple next smaller and next greater than the sum. The first remainder will then indicate the days which have elapsed since the preceding mean new moon, and the second those before the next following. The limits of D for a central eclipse will then be,

D between \pm 14^d.2: an eclipse certain. D between \pm 20^d.8: an eclipse possible.

D between \pm 8d.o: a central eclipse certain. D between \pm 14d.3: a central eclipse possible.

If the occurrence of the eclipse is still doubtful, the limits may be narrowed by applying to D the further correction taken from Table III, of which the argument is the day of the fictitious year, already found from Table II. This table only holds good within two or three centuries of the present time; but it may be used for other centuries by simply increasing the argument by one day for each century before the nineteenth. Using the corrected values of D, the limits will be,

 \pm 16^d.1: an eclipse certain. \pm 18^d.9: an eclipse possible.

 \pm 9^d.9: a central eclipse certain. \pm 12^d 4: a central eclipse possible.

To find the central eclipse of the series to which the required one belongs, take one of the values of P corresponding most nearly to D in the following table:-

1	1			1				l		-				1	:	ı		
D	0.5	1.0	1.4	1.9	2.4	2.9	3.4	3.8	4.3	4.8	5 · 3	5.8	6.2	6.7	7.2	7.7	8.2	8.6
P	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
T	18	36	54	72	90	108	126	111	162	180	198	216	234	252	270	258	307	325
D	9.1	9.6	10.1	10.6	11.1	11.5	12.0	12.5	13.0	13.5	13.9	14.4	14.9	15.4	15.8	16.3	16.8	17.3
P	19	20	21	22	23	2.1	25	26	27	28	29	30	31	32	33	34	35	36
T	3+3	361	379	397	415	433	451	469	487	505	523	541	539	577	596	614	632	650
,	_		!		!		l	-		!	l	l		l	l	l	i	i

If D is positive, subtract one of the nearest values of T from the number of the year; if negative, add it, and we shall hit very nearly upon the date of central eclipse found in Table V or VI, according to the node, or upon a date differing by a multiple of 15 years. The corresponding value of P will be the number of periods of 18 114 between the date in Table V or VI and the date of the eclipse sought.

It is to be noted that if the value of T thus found carries the central date without the limits - 770 and + 2360, a value of P and T small

enough to bring the date within these limits will be necessary.

TABLE V.—Mean Elements of Eclipses at Ascending Node.

The second and third columns of Tables V and VI give, with some exceptions noted on page -8, the dates of those mean new moons which occur nearest to the nodes. The four columns following give the values of the four principal arguments for these dates.

The number of the conjunction point at which an eclipse occurs may be found from the results of Tables I, II, and IV, as follows:—Put t for the fraction of a century which has elapsed since the last preceding passage of a conjunction point through the corresponding node, as found on p. 14, and n_o for the number of that point. Then, the quantity

 $n_0 + 1\frac{1}{3}t - c.641$

will be nearly an integer, which integer will be the number of the point sought, and the argument for Table V or VI.

TABLE VI.—Mean Elements of Eclipses at Descending Node.

In Table VI the values of u_o are given in the last column as if counted from the descending node, but, to make the notation uniform, these are considered as values of $u_o = 180^\circ$, u_o being always counted from the ascending node.

TABLE VII.—Reduction of Quantities in the Preceding Tables to Corresponding Conjunctions in Other Cycles.

Having identified the central eclipse of the series to which the required one belongs, the times and arguments from Table V or VI are to be reduced to the required date, for the number of periods elapsed, by means of Table VII. Here the time is to correspond to the middle of the elapsed interval. If the eclipse examined precedes the central one in time, the signs of all the quantities are to be changed.

Table VII.—Reduction of Quantities in the Preceding Tables, etc.—Continued.

		g			g					

In Tables XVIII and XIX, the numbers have the sign given with them near the ascending node, and the opposite sign near the descending node.

The algebraic sum of the numbers taken from the three tables, XVIII to XX, is the value of y_2 , the ordinate of the point in which the axis of the shadow intersects the fundamental plane, at the moment of true ecliptic conjunction. This ordinate is reckoned in a direction perpendicular to the ecliptic.

In Table XX, the algebraic sign of the numbers is the same as that of $\sin u_1$. Near the descending node u_1 differs little from 180°; hence near the ascending node the number from Table XX has the same sign as u_1 ; near the descending node the opposite sign of u_1-180° .

TABLE XX.—Hor. Arg., g; Vertical Arg., u,.

When the argument g is at the bottom of the page, or is negative, g' is to be sought for at the right.

The algebraic sum of the numbers from Tables XXI and XXII is the hourly variation of the co-ordinate x_2 of the point in which the axis of the shadow intersects the fundamental plane.

	1	g			g					

In Tables XVIII and XIX, the numbers have the sign given with them near the ascending node, and the opposite sign near the descending

The algebraic sum of the numbers taken from the three tables, XVIII to XX, is the value of y_2 , the ordinate of the point in which the axis of the shadow intersects the fundamental plane, at the moment of true ecliptic conjunction. This ordinate is reckoned in a direction perpendicular to the ecliptic.

In Table XX, the algebraic sign of the numbers is the same as that of $\sin u_1$. Near the descending node u_1 differs little from 180° ; hence near the ascending node the number from Table XX has the same sign as u_1 ; near the descending node the opposite sign of u_1-180° .

TABLE XX.—Hor. Arg., g; Vertical Arg., u,.

				<i>y</i> 3° = ⊣	+ (5.245 — 0.330	$\cos g$) $\sin u_1$.

When the argument g is at the bottom of the page, or is negative, g' is to be sought for at the right.

The algebraic sum of the numbers from Tables XXI and XXII is the hourly variation of the co-ordinate x_2 of the point in which the axis of the shadow intersects the fundamental plane.

The algebraic sum of the numbers from Tables XXIII and XXIV is the radius of the shadow-cone on the fundamental plane. If this radius is negative, it indicates a total eclipse; if positive, an annular one.

To find the radius of the penumbra, the sum of the numbers is to be increased by 0.5460.

TABLE XXV.—Angle of Shadow Cone.

Table XXV gives the angle of the shadow cone and its logarithm.

Table XXVI gives the sun's equation of the centre. By applying this quantity to L, the sun's mean longitude, we obtain O, its true longitude.

TABLE XXVII.—Reduction from O's Longitude to O's Right Ascension.

Table XXVII gives, with argument ⊙, a quantity which, when added to the equation of the centre (Table XXVI), will be the equation of time, E, expressed in degrees and hundredths.

Table XXVIII — Coefficients for Besselian Co-ordinates of Shadow Axis.

Table XXVIII gives the coefficients by which to express the co-ordinates, x_1 and y_1 , of the shadow axis on the fundamental plane. These correspond to the co-ordinates x and y of the Besselian theory of eclipses and of the American Ephemeris. The expressions are:—

$$x_1 = a y_2^{\circ} + b x_2^{\prime} t,$$

 $y_1 = a' y_2^{\circ} + b' x_3^{\prime} t,$

 y°_{3} having been obtained from Tables XVIII to XX, and x'_{3} from Tables XXI and XXII.

Table XXIX gives, with argument \odot , the value of the sun's declination, d, that of d_1 , the reduced declination, and that of $\frac{1}{\rho_1}$ for computing the central line on the earth's surface.

 x'_2 .5798 .0008

0.5806

As an example of the use of the Tables, we shall examine what eclipses of the sun were visible during the year B. C. 584. From Table I, we find the argument of Table II to be 79.772. From Table II, the times of conjunction of the mean sun with the node are found to be 144d.8 for ascending and 318d.1 for descending node. The values of D show that there were two central eclipses, of which the second was central only in the southern hemisphere. We therefore consider only the first one, which is the celebrated eclipse of Thales:

The last point of the shadow-path is between 4° and 6° south of the region within which the celebrated battle must have been fought, which was supposed to have been stopped by this eclipse. This large deviation is due to the corrections which have been applied to Hansen's mean longitude of the moon. If these corrections are well founded, the sun set upon the combatants about nine tenths eclipsed.

A TRANSFORMATION

OF

HANSEN'S LUNAR THEORY

COMPARED WITH THE

THEORY OF DELAUNAY.

BY

SIMON NEWCOMB, SUPERINTENDENT AMERICAN EPHEMERIS,

AIDED BY

JOHN MEIER,
ASSISTANT AMERICAN EPHEMERIS.

TRANSFORMATION OF HANSEN'S LUNAR THEORY.

The numerical computation of the inequalities in the moon's motion executed by Hansen was probably the greatest step taken in recent times toward placing the theory of the lunar perturbations on an accurate numerical basis. It was the step which first rendered it certain that any discrepancy between the theoretical and observed values of the inequalities produced by the sun arose from some other cause than errors in theory. The theoretical values to which it led must be considered the most accurate which astronomy now possesses.

The only theory which can compete with Hansen's is that of Delaunay. Here the coefficients are developed in series converging so slowly that some of the results are still a little doubtful, notwithstanding the great extent to which the approximation was carried. It may be expected that the numerical theory on which Sir George Airy is now engaged will form yet another step in advance, in which nothing will be wanting for the purposes of accurate astronomy, so that three theories of the highest order of accuracy will ultimately be available for the construction of lunar tables. The work in question being still unfinished, the results of Hansen and Delaunay are the only ones now available.

Unfortunately, the theory of Hansen cannot be directly compared with those which have preceded it, owing to the peculiar form of the variables in which the co-ordinates of the moon are expressed. In saying this, I do not contest the proposition that this form has advantages. But, apart from the question of its merits in form, it becomes important to have the means of making a direct comparison of Hansen's theory with that of his predecessors and colaborers, who have expressed the co-ordinates of the moon directly in terms of the time. This has twice been partially done: by the writer in the Comptes Rendus for 1868, I (Tome LXVI, p. 1197), and, independently, by Schjellerup, in a paper published in 1874 by the Danish Academy of Sciences. Both depend on data for the transformation given by Hansen himself, which, though they may be accurate enough to give an idea of the agreement between the theories of Hansen and Delaunay, cannot be regarded as sufficiently precise for a satisfactory transformed theory. The object of the present paper is to make a transformation which shall faithfully represent HANSEN'S latest theory, and be expressed in arguments depending directly on the time. 59

◊ 1.

EXPRESSION OF THE MOON'S LONGITUDE.

In Hansen's theory the moon's longitude is represented in the following form. Put

- g, the moon's mean anomaly;
- g', the sun's mean anomaly;
- ω , the distance from the node to the perigee;
- ω' , the distance from the node to the solar perigee;
- π , the longitude of the perigee;
- e, the eccentricity of the moon's orbit, as used by Hansen;
- $n\delta z$, the Hansenian perturbations of mean anomaly;
 - s, the Hansenian perturbations of latitude;
 - I, the inclination of the moon's orbit.

Then put, as auxiliary quantities,

$$f = \text{elta } (e,g + n \delta z)$$
, the true anomaly;

$$R = -\tan^2 \frac{1}{2} I \sin 2 (f + \omega) + \frac{1}{2} \tan^4 \frac{1}{2} I \sin 4 (f + \omega) - \text{etc.},$$

the reduction to the ecliptic;

$$R' = -s \frac{\tan I \cos (f + \omega)}{1 - \sin^2 I \sin^2 (f + \omega)}$$

$$-o'' \cdot 397 \sin 2 \omega$$

$$-1'' \cdot 198 \sin (2 g' + 2 \omega')$$

$$-o'' \cdot 285 \sin (2 g - 4 g' + 2 \omega - 4 \omega'),$$

the inequalities of this reduction.

Then, for the moon's longitude,

$$L = f + \pi + R + R'.$$

The latitude, β , is given by the equation

$$\sin \beta \equiv \sin I \sin (f + \omega) + s$$
.

In presenting Hansen's results in the form of a complete and exact numerical theory, several precautions have to be taken. In the first place, all the results must, so far as possible, depend upon or be reduced to one and the same homogeneous set

of elements. In the next place, those inequalities which express the solution of the problem of three bodies, considered as material points, must be separated from inequalities arising from other sources, such, for instance, as the distance between the moon's centres of gravity and figure, and the ellipticity of the earth.

Three values of the eccentricity appear in Hansen's theory and tables:

- (1) A provisional or ideal eccentricity, with which the inequalities were originally computed.
- (2) An apparent eccentricity, which he found to represent the observed motion of the moon's centre of figure, and used in his tables.
- (3) A theoretical eccentricity of the true orbit described by the moon's centre of gravity.

These three values of the element are:—

(1)
$$e = .05490079$$

(2)
$$e = .05490807$$

(3)
$$e = .05489959$$

According to Hansen's view it is the third value which should be used in computing the moon's perturbations; but as he actually used the first value, it is the one which we should employ in the transformation.

In the case of the inclination there are three corresponding values, with an additional complication arising from the question whether we shall add to the inclination a term in the perturbations, 2".705 $\sin(g + \omega)$, having the mean argument of latitude as its argument.

Omitting this term, the values of the inclination will be:-

(1)
$$I = 5^{\circ} 8' 48''$$

(2)
$$I = 5^{\circ} 8' 43''.66$$

(3)
$$I = 5^{\circ} 8' 39''.96$$

Here, again, it is only the first value with which we are concerned in the transformation, because it is the one employed by Hansen in computing the perturbations.

The Hansenian perturbation $n\delta z$ is an explicit function of g, g', ω and ω' . So far as the longitude is concerned, our present problem is to express f, R and R', and thence L, as explicit functions of the above four quantities. If we put:—

$$z = g + n\delta z$$

 e_1 , e_2 , e_3 , etc., the coefficients of $\sin z$, $\sin 2z$, etc. in the development

of elta (e, z), we shall have,

$$f = z + e_1 \sin z + e_2 \sin 2z + \text{etc.}$$

If, then, we put $g + n\delta z$ for s, develop in powers of $n\delta z$, call $(e, g)_0$ the part of f independent of $n\delta z$, and $(e, g)_i$ the coefficient of $(n\delta z)^i$ in f, we shall have,

$$(e,g)_0 = g + e_1 \sin g + e_2 \sin 2g + e_3 \sin 3g + e_4 \sin 4g + \text{etc.}$$

$$(e,g)_1 = 1 + e_1 \cos g + 2e_2 \cos 2g + 3e_3 \cos 3g + \text{etc.}$$

$$(e,g)_2 = -\frac{1}{2}e_1 \sin g - \frac{2^2}{2}e_2 \sin 2g - \frac{3^2}{2}e_3 \sin 3g - \text{etc.}$$

$$(e,g)_3 = -\frac{1}{2\cdot 3}e_1 \cos g - \frac{2^3}{2\cdot 3}e_2 \cos 2g - \frac{3^3}{2\cdot 3}e_3 \cos 3g - \text{etc.}$$

$$(e,g)_4 = \frac{1}{2\cdot 3\cdot 4}e_1 \sin g + \text{etc.}$$
etc.

The coefficients e_1 , e_2 , etc., are dependent on the eccentricity. The well-known analytical values, and the numerical values obtained by putting e = .05490079, are:

$$e_{1} = 2 e \qquad -\frac{1}{4} e^{3} + \frac{5}{96} e^{5} = .10976024 = 22639''.676$$

$$e_{2} = \frac{5}{4} e^{2} - \frac{11}{24} e^{4} + \frac{17}{192} e^{6} = .00376346 = 776''.269$$

$$e_{3} = \frac{13}{12} e^{3} - \frac{43}{64} e^{5} = .00017893 = 36''.907$$

$$e_{4} = \frac{103}{96} e^{4} - \frac{451}{480} e^{6} = .0000972 = 2''.005$$

$$e_{5} = \frac{1097}{960} e^{5} = .00000057 = 0''.118$$

$$e_{6} = \frac{1223}{960} e^{6} = .0000004 = 0''.007$$

The value of $n\delta z$ is taken, not from Hansen's tables, but from his revised results given in the *Darlegung**. They are found in Part I, pp. 409-411, and Part II, pp. 224, 242, 258, and 268, and, for convenience of reference, are all collected in Table I of the present paper. In this table are given also the powers of $n\delta z$, the computations of which were all made in duplicate, that of the square being executed by two independent computers.

We thus have all the data for the numerical value of f, the formula for which is,

$$f = (e, g)_0 + (e, g)_1 \, n \, \delta z + (e, g)_2 \, (n \, \delta z)^2 + \text{etc.}$$
 (1)

Consider next the first term of R, which we may call R₁. We have

$$R_1 = - \tan^2 \frac{1}{2} I \sin (2 f + 2 \omega),$$

which is also to be developed in powers of $n\delta z$.

^{*} Under this title reference is made to Hansen's two papers, Darlegung der theoretischen Berechnung der in den Mondtafeln angewandten Störungen, in the Abhandlungen der königlich-sächeischen Gesellschaft der Wissenschaften. Band IX, XI.

If we substitute for f its value in terms of e and z, and develop in powers of e, we find *:—

$$R_{1} = -\tan^{2}\frac{1}{2}I \times \begin{cases} \frac{1}{24}e^{4} & \sin(-2z+2\omega) \\ +\frac{1}{12}e^{3} & \sin(-z+2\omega) \\ +\left(\frac{3}{4}e^{2}+\frac{1}{8}e^{4}\right)\sin 2\omega \\ +\left(-2e+\frac{7}{4}e^{3}\right)\sin(-z+2\omega) \\ +\left(1-4e^{2}+\frac{55}{16}e^{4}\right)\sin(-2z+2\omega) \\ +\left(2e-\frac{27}{4}e^{3}\right)\sin(-3z+2\omega) \\ +\left(\frac{13}{4}e^{2}-\frac{259}{24}e^{4}\right)\sin(-4z+2\omega) \\ +\frac{59}{12}e^{3} & \sin(-5z+2\omega) \\ +\frac{115}{16}e^{4} & \sin(-6z+2\omega) \end{cases}$$

If, in this equation, we substitute for e and I their numerical values and then differentiate with respect to z, so as to obtain the coefficients of the powers of $n\delta z$, putting

$$R_1 = R_{1,0} + R_{1,1} n \delta z + R_{1,2} (n \delta z)^2 + \text{etc.}$$

we have

$$\begin{array}{l} {\rm R_{1,0}} = - & {\rm o''.006~sin} \; (-g+2\,\omega) \\ - & {\rm o''.942~sin} \; (& 2\,\omega) \\ + & 45''.627~sin} \; (& g+2\,\omega) \\ - & 411''.626~sin} \; (& 2\,g+2\,\omega) \\ - & 45''.281~sin} \; (& 3\,g+2\,\omega) \\ - & 4''.040~sin} \; (& 4\,g+2\,\omega) \\ - & {\rm o''.338~sin} \; (& 5\,g+2\,\omega) \\ - & {\rm o''.027~sin} \; (& 6\,g+2\,\omega) \\ \end{array}$$

^{*} Tables of this and the other developments in the elliptic motion have been given by Professor CAYLEY in the *Memoirs of the Boyal Astronomical Society*, Vol. XXIX, but the above development was executed independently before the applicability of Professor CAYLEY'S formulæ was remarked.

$$R_{1,2} = -.00011 \sin (g+2\omega) +.00399 \sin (2g+2\omega) +.00099 \sin (3g+2\omega) +.00016 \sin (4g+2\omega) R_{1,3} = +.0027 \cos (2g+2\omega) +.0010 \cos (3g+2\omega)$$

In the same way, putting

$$R_2 = \frac{1}{2} \tan^4 \frac{1}{2} I \sin (4 f + 4 \omega)$$

we have by substituting for f its value in z, and developing in powers of e,

$$\sin (4f + 4\omega) = \frac{\frac{11}{2}e^2 \sin (2z + 4\omega)}{-4e \sin (3z + 4\omega)} + (1 - 16e^2) \sin (4z + 4\omega) + 4e \sin (5z + 4\omega) + \frac{21}{2}e^2 \sin (6z + 4\omega)$$

Putting as before,

$$R_2 = R_{20} + R_{21} n \delta z + R_{22} (n \delta z)^2 + \text{etc.}$$

we find by substituting the numerical values of I and e

$$R_{2,0} = + o''.007 \sin (2 g + 4 \omega)$$

$$- o''.092 \sin (3 g + 4 \omega)$$

$$+ o''.400 \sin (4 g + 4 \omega)$$

$$+ o''.092 \sin (5 g + 4 \omega)$$

$$+ o''.013 \sin (6 g + 4 \omega)$$

$$R_{2,1} = -.000 001,3 \cos (3 g + 4 \omega)$$

$$+ .000 007,8 \cos (4 g + 4 \omega)$$

$$+ .000 002,2 \cos (5 g + 4 \omega)$$

The terms of $R_{2,2} (n \delta z)^2$ are less than 0".001.

The coefficient of -s tan I in R' is, with sufficient accuracy,

$$\cos (f + \omega) \left[1 + \sin^2 I \sin^2 (f + \omega) \right]$$

or

$$\left(1+\frac{1}{4}\sin^2 I\right)\cos \left(f+\omega\right)-\frac{1}{4}\sin^2 I\cos \left(3f+3\,\omega\right).$$

By the developments of the elliptic motion we have,

$$\cos (f + \omega) = -\frac{1}{12} e^3 \cos (-2z + \omega)$$

$$-\frac{1}{8} e^2 \cos (-z + \omega)$$

$$-e \cos \omega$$

$$+ (1 - e^2) \cos (z + \omega)$$

$$+ (e - \frac{5}{4} e^3) \cos (2z + \omega)$$

$$+ \frac{9}{8} e^2 \cos (3z + \omega)$$

$$+ \frac{4}{3} e^3 \cos (4z + \omega)$$

$$\cos (3f + 3\omega) = \frac{21}{8} e^2 \cos (z + 3\omega)$$

$$- 3e \cos (2z + 3\omega)$$

$$+ (1 - 9e^2) \cos (3z + 3\omega)$$

$$+ 3e \cos (4z + 3\omega)$$

$$+ 3e \cos (4z + 3\omega)$$

$$+ \frac{51}{8} e^2 \cos (5z + 3\omega)$$

If we represent by S the coefficient of s in R', that is,

$$S = -\tan I \cos (f + \omega) \{ 1 + \sin^2 I \sin^2 (f + \omega) \},$$

and suppose

$$S = S_o + S_1 n \delta z + S_2 (n \delta z)^2,$$

we shall have,

$$S_{o} = +.000034 \cos (-g + \omega) +.004955 \cos \omega -.089978 \cos (g + \omega) -.004936 \cos (2g + \omega) -.000306 \cos (3g + \omega) -.000020 \cos (4g + \omega) -.000030 \cos (2g + 3\omega) +.000176 \cos (3g + 3\omega) +.000030 \cos (4g + 3\omega) +.000004 \cos (5g + 3\omega) S_{1} = +.0900 \sin (g + \omega) +.0099 \sin (2g + \omega) +.0009 \sin (3g + \omega) S_{2} = +.045 \cos (g + \omega) +.010 \cos (2g + \omega)$$

Multiplying these several expressions by Hansen's s, we find the value of $s S_o$, etc., given in Table II.

Collecting all the coefficients of the powers of $n \delta z$, we find the following expressions for the moon's true ecliptic longitude, as a function of $n \delta z$:—

$$L = L_0 + L_1 n \delta z + L_2 (n \delta z)^2 + \text{etc.}$$

Terms independent of n & z.

$$\begin{array}{l} \mathbf{L_o} = g + \pi \\ + 22639''.676 \sin g \\ + {}^{\circ}776''.269 \sin 2g \\ + 36''.907 \sin 3g \\ + 2''.005 \sin 4g \\ + 0''.118 \sin 5g \\ + 0''.007 \sin 6g \\ - 0''.006 \sin (-g + 2\omega) \\ \left\{ \begin{array}{l} - 0''.942 \\ - 0''.397 \\ \end{array} \right\} \sin 2\omega \\ + 45''.627 \sin (g + 2\omega) \\ - 411''.626 \sin (2g + 2\omega) \\ - 45''.281 \sin (3g + 2\omega) \\ - 0''.338 \sin (5g + 2\omega) \\ - 0''.338 \sin (5g + 2\omega) \\ - 0''.027 \sin (6g + 2\omega) \\ + 0''.007 \sin (2g + 4\omega) \\ - 0''.092 \sin (3g + 4\omega) \\ + 0''.400 \sin (4g + 4\omega) \\ + 0''.400 \sin (4g + 4\omega) \\ + 0''.992 \sin (5g + 4\omega) \\ + 0''.992 \sin (5g + 4\omega) \\ - 0''.993 \sin (2g + 2\omega) \\ - 0''.285 \sin (2g + 2\omega) \\ - 0''.285 \sin (2g - 4g + 2\omega - 4\omega) \\ + 8 \, \mathbb{S}_0. \end{array}$$

Coefficient of $n \delta z$.

[The comma points off six places of decimals.]

$$\begin{array}{l} \mathbf{L_1} = & \mathbf{I} \\ & + .109760, 2 \cos g \\ & + .007526, 9 \cos 2g \\ & + .000536, 8 \cos 3g \\ & + .00002, 8 \cos 5g \\ & + .000021, 2 \cos (g + 2\omega) \\ & - .003991, 2 \cos (2g + 2\omega) \\ & - .000058, 6 \cos (3g + 2\omega) \\ & - .000008, 2 \cos (5g + 2\omega) \\ & - .000000, 8 \cos (6g + 2\omega) \end{array}$$

- .000001,3
$$\cos (3g + 4\omega)$$

+ .000007,8 $\cos (4g + 4\omega)$
+ .000002,2 $\cos (5g + 4\omega)$
+ $s S_1$
L₂ = - .05488 $\sin g$
- .00753 $\sin g$
- .00080 $\sin g$
- .00080 $\sin g$
- .00011 $\sin (g + 2\omega)$
+ .00399 $\sin (g + 2\omega)$
+ .00099 $\sin (g + 2\omega)$
+ .00016 $\sin (g + 2\omega)$
+ .00016 $\sin (g + 2\omega)$
+ .00016 $\sin (g + 2\omega)$
+ .00016 $\sin (g + 2\omega)$
+ .00016 $\sin (g + 2\omega)$
+ .00016 $\sin (g + 2\omega)$
+ .00016 $\sin (g + 2\omega)$
+ .0010 $\cos (g + 2\omega)$
+ .0010 $\cos (g + 2\omega)$

The several parts of this expression for L are given in Table II, omitting the following terms, which are, however, all included in the column giving the concluded coefficients in L:—

- 1. The terms of L_o, explicitly given in the first of the preceding equations.
- 2. The expressions for $n\delta z$, $(n\delta z)^2 \times s S_2$, $(n\delta z)^3 \times R_{1,3}$, and $(n\delta z) \times R_{2,1}$.

The values of the last three expressions are as follows, the numbers within the parentheses being coefficients of g, g', ω , and ω' , respectively:—

$n \delta z \times \mathrm{R}_{2,1}$	$(n \delta z)^2 \times s S_2$	$(n \delta z)^3 \times R_1, _3$
. "	<i>"</i> =	=
$001 \sin (3, 3, 2, 2)$	$002 \sin (0, -2, 2, -2)$	∞ 1 sin (2, 1, 2, 0)

In Table II the column "Sum" contains the sums of the terms actually given in the preceding columns of the table.

The next column gives the complete coefficient of each term in the ecliptic longitude, and is formed by adding to the column "Sum" the omitted terms just referred to.

The last column gives, for the larger terms, the elements which they principally contain as factors. If these elements be changed, the coefficients must be changed by corresponding quantities.

₫ 2.

REDUCTION OF THE PRECEDING EXPRESSIONS TO UNIFORM ELEMENTS, AND COMPARISON WITH DELAUNAY.

The coefficients of the preceding inequalities contain as factors certain elements for which different investigators adopt different values. It is essential to a clear presentation of results that they should be reduced to a uniform and well-defined set of elements having given values We therefore commence by reducing the theories of both Hansen and Delaunay to such a system. The elements principally referred to are—

- (α) The ratio of the mean motions of the sun and moon.
- (β) The lunar eccentricity.
- (γ) The solar parallax.
- (δ) The solar eccentricity.
- (ε) The inclination of the moon's orbit.

Really, all these elements are contained in all the inequalities in a very complex manner. But there is so little doubt about their true numerical values that it is only necessary to take account of their changes when they appear as factors in coefficients of considerable magnitude. The extent to which each term is affected can be roughly seen from its analytic expression given by Delaunay at the end of his *Theorie du Mouvement de la Lune*, Tome II. We take up the several elements in order.

- (α) Ratio of mean motions. This element is so certain that no reduction need be made on account of it. It is true that theoretical motions of the lunar node and perigee must implicitly enter in connection with this element. But, from a rough examination of Hansen's integration coefficients on pp. 350-352 of his Darlegung, I
- do not think any of the larger coefficients will be affected by as much as $\frac{1}{100000}$ of their entire amount by any admissible change of these motions.
- (β) Eccentricity of moon's orbit. The eccentricities used by the two investigators are not directly comparable, but may be most conveniently compared by reducing each to the coefficient of g in the expression for the moon's ecliptic longitude. Delaunay uses Airy's value, given in his last paper on the elements of the moon's orbit.*

 Hansen corrected his eccentricity for use in his tables, as already mentioned. The writer obtained a small but well-marked correction to Hansen's value from the Green-

wich observations 1846-'74, and the Washington observations 1862-'74. The four values of the coefficient in question are:—

Although there is no reasonable doubt that the eccentricity of Hansen's tables requires a negative correction, it will be adopted for the purposes of comparison because it is now the standard of the ephemerides with which subsequent comparisons must be made. All the terms having e as a coefficient, must therefore be increased by the factor

$$\frac{.00000728}{.05490} = .0001326,$$

and those having e^2 by double this factor. The coefficients in e must, in Delaunay's theory, be increased by the factor

$$\frac{1''.09}{22639''} = .0000482.$$

(y) Solar parallax. Hansen's theory does not set out with a definite solar parallax, but with a ratio of the mean distances of the sun and moon, which ratio again is not the usual one, because Hansen's a and a' are the same functions of the motion of mean anomaly that the usual a and a' are of the sidereal motions. We must therefore adopt an indirect process for finding the relation of solar parallax and parallactic equation on his theory. He finds that his theoretical coefficient has to be multiplied by the factor 1.03573 to make it agree with observation; and then, in § 266 of his Darlegung, he deduces the solar parallax S''.9159. Dividing this parallax by the preceding factor, we conclude that the parallax of his theory is:—

In turning his theory into numbers Delaunay used 8".75. The parallax to which both theories will be actually reduced is:—

Hence, Hansen's terms having the parallax as a factor must be increased by the factor

and Delaunay's by the factor

.01120.

(δ) The solar eccentricity. The solar eccentricity of Hansen's theory is:—

$$e' = 0.01679226$$
 (Epoch 1800).

^{*} Papers published by the Commission on the Transit of Venus. Part III.

Delaunay uses Le Verrier's value:-

$$e' = 0.01677106$$
 (Epoch 1850).

In strictness these two values are not comparable, owing to the different form of Hansen's solar theory; but since Hansen neglects perturbations of the earth's motion in his lunar theory, it may be assumed that there will be no difference between the form in which the eccentricity enters into the two theories. If we carry Le Verrier's eccentricity back to 1800 with his secular variation, we shall have:—

$$e' = 0.01679228$$
 (Epoch 1800).

This may be regarded as absolutely identical with Hansen's value for the same epoch. So, adopting 1800 as the epoch, we have only to increase Delaunay's coefficients in e' by the factor

$$\frac{.00002122}{.01677} = .001265.$$

Or, we may reduce Hansen's values to 1850 by dividing them by 1.001265, when they will be comparable with Delaunay's.

The theories of Hansen and Delaunay, thus reduced to a uniform and consistent set of elements, are given and compared in Table III. Delaunay's results are frequently doubtful by a small fraction of a second, owing to the slow convergence of the series in powers of m, and the table has been arranged so as to show the extent of the uncertainty thus arising.

Following the indices expressing the arguments are given, first, Hansen's coefficients formed from the values in Table II by multiplying by the appropriate factors for reduction already given. They are only given to o".o1, but should the thousandth of seconds be required they are readily obtainable.

The corresponding coefficients of Delaunay are derived principally from his presentation of numerical results in the additions to the *Connaissance des Temps* for 1869. On pages 11 to 21 of that paper are given the sums of the terms in each coefficient which were actually computed by him. The parallactic terms, as given by Delaunay, are still to be multiplied by $\frac{1-\lambda}{1+\lambda}$, λ being the ratio of the mass of the moon to that of

the earth. Putting, with Hansen, $\lambda = \frac{1}{80}$, the coefficient will be $\frac{79}{81}$. The sums, corrected for this coefficient and for difference of elements, are given in the column Delaunay (1). Had all the appreciable terms been actually computed, these coefficients would have been the definitive ones of Delaunay's theory. But it was frequently found that the terms, even of the ninth order, where the development ceased, were still appreciable; it was, therefore, necessary to estimate the probable sum of the omitted terms of higher orders from the law of the series as observed in the terms actually computed. These estimates can have no true mathematical foundation,

because there is no proof of the actual law of the series.* Still, there is a high degree of probability in favor of each one being at least a rude approximation to the truth. A rigorous computation would probably show that a majority differed less than \(\frac{1}{4} \) of their amount from the true values, though here and there one might be found entirely illusory. The coefficients of longitude, modified by these estimated additions, are given by Delaunay on pages 38-40 of the paper referred to, and are reproduced, with the necessary corrections for changes of elements, in the column Delaunay (2).

The difference of these results, given in the next column, is the correction apparently applied by Delaunar for the uncomputed terms. It will be noted that we have no independent statement of these terms to refer to, and can only infer their values from the differences between the printed results (1) and (2)

Finally, we have the difference, Hansen minus Delaunay (2) showing the discrepancies still outstanding between the two theories Each one can judge for himself how far these discrepancies arise from the uncertainty of Delaunay's semi-empirical corrections, and how far from errors in the two theories.

One or two terms are worthy of a special examination, and among these the parallactic equation takes the first rank, as upon it depends the value of the solar parallax to be derived from a given observed value of this equation. Arranging Delaunay's terms according to the power of m, which enters as a factor, the result will be that given below under the head P_1 . Delaunay omits terms in y^2 after m^3 , and terms in e^2 after m^5 . Correcting the result for an estimated value of these terms, derived by induction, we shall have those given under the head P_2 . It will be seen that the terms follow a nearly regular law up to m^6 , but that m^7 deviates from this law. Assuming this term to be in error, and estimating the value of it and the higher terms as those of

a geometrical progression with the ratio $\frac{4}{10}$ we have the results P₃.

Our choice must lie between the results P₂ and P₃. If we adopt the former we may add o".26 as an estimate of omitting terms giving:—

$$P = -127''.24$$
; $P' = \frac{79}{81} P = -124''.10$.

^{*}It may be remarked that in the series for the secular acceleration DELAUNAY found the terms of a higher order actually to change their sign, directly contrary to the estimate which would have been formed from those of a lower order.

If we adopt the latter we have

$$P = -127''.08;$$
 $P' = \frac{79}{81}P = -123''.94.$

Multiplying by the coefficient 1.0112 to reduce to the parallax 8".848 the result will be:—

$$\begin{array}{ccc} (2) & -125''.49 \\ (3) & -125''.33. \end{array}$$

Hansen's coefficient, — 125".43, falls between these results and may be regarded as certainly correct within less than o".1.

The other term referred to is that depending on the argument:-

$$g-g'+2\omega-2\omega'$$

of which the principal parts of the coefficient are, in Delaunay's theory,-

Delaunar seems to have taken I".18 as the probable sum of the omitted terms, whereas they should have been taken as o".94 to agree with Hansen.

§ 3.

LATITUDE.

Taking Hansen's expression for the moon's latitude:-

$$\sin \beta \equiv \sin I \sin (f + \omega) + s;$$

the first step is to form the expression $\sin (f + \omega)$ in terms of g, ω , etc. This may be done in two ways. By the first we express the required quantity as a function of z, and

then put $g + n\delta z$ for g and develop in powers of $n\delta z$. By the theory of elliptic motion the expression of $\sin (f + \omega)$ in terms of z will be

$$\sin (f + \omega) = \frac{625}{9216} e^{6} \sin (-5z + \omega)$$

$$- \frac{1}{15} e^{5} \sin (-4z + \omega)$$

$$+ \left(-\frac{9}{128} e^{4} + \frac{9}{320} e^{6}\right) \sin (-3z + \omega)$$

$$+ \left(-\frac{1}{12} e^{3} + \frac{1}{48} e^{5}\right) \sin (-2z + \omega)$$

$$+ \left(-\frac{1}{8} e^{2} + \frac{1}{48} e^{4} + \frac{37}{3072} e^{6}\right) \sin (-z + \omega)$$

$$- e \sin \omega$$

$$+ \left(1 - e^{2} + \frac{7}{64} e^{4} - \frac{5}{288} e^{6}\right) \sin (z + \omega)$$

$$+ \left(e - \frac{5}{4} e^{3} + \frac{17}{48} e^{5}\right) \sin (2z + \omega)$$

$$+ \left(\frac{9}{8} e^{2} - \frac{27}{16} e^{4} + \frac{765}{1024} e^{6}\right) \sin (3z + \omega)$$

$$+ \left(\frac{4}{3} e^{3} - \frac{7}{3} e^{5}\right) \sin (4z + \omega)$$

$$+ \left(\frac{625}{384} e^{4} - \frac{625}{192} e^{6}\right) \sin (5z + \omega)$$

$$+ \frac{81}{40} e^{5} \sin (6z + \omega)$$

$$+ \frac{117640}{46080} e^{6} \sin (7z + \omega).$$

If we now substitute for z, $g + n \delta z$, for e its numerical value, and develop, putting:—

$$\sin I \sin (f + \omega) = F_0 + F_1 n \delta z + F_2 (n \delta z)^2 + F_3 (n \delta z)^3$$

we shall have

$$F_{0} \text{ (in arc)} = - \qquad o'' \text{ ol 2 sin } (-3 g + \omega)$$

$$- \qquad o''.255 \sin (-2 g + \omega)$$

$$- \qquad 6''.968 \sin (-g + \omega)$$

$$- \qquad 1015''.834 \sin \omega$$

$$+ \qquad 18447''.342 \sin (g + \omega)$$

As a check upon the value of $\sin I \sin (f + \omega)$ a second method of computing it was adopted, as follows. Let us put:—

$$\delta f = f - g$$
.

Then

$$\sin (f + \omega) = \sin (g + \omega + \delta f)$$

$$\cdot = \cos \delta f \sin (g + \omega)$$

$$+ \sin \delta f \cos (g + \omega).$$

From the numerical value of δf already given the powers of this quantity were formed, and thence its cosine and sine from the formulæ:—

$$\cos \delta f = I - \frac{\delta f^2}{I.2} + \text{etc.}$$

$$\sin \delta f = \delta f - \frac{\delta f^3}{I.2.3} + \text{etc.}$$

These expressions were then multiplied by the sine and cosine of $(g + \omega)$.

The mean difference between the coefficients in $\sin I \sin (f + \omega)$ found by the two methods was less than 0".003, the largest one being ".010.

Adding Hansen's s to this expression we have the value of $\sin \beta$. Then β itself is obtained by the formula

$$\beta \equiv \sin \beta + \frac{1}{6} \sin^3 \beta + \frac{3}{40} \sin^5 \beta$$
.

The principal parts of β are given in Table IV, of which the columns referring to Hansen's theory seem to need no explanation.

REDUCTION OF THE LATITUDE AND COMPARISON WITH DELAUNAY.

All the terms of the latitude contain the inclination of the moon's orbit as a factor, and are therefore to be multiplied by such a constant coefficient that the principal term of the latitude shall agree with observation. The transformed expressions of Hansen, given in Table IV, lead to a consistent theory in which the coefficient of the principal term of the latitude is 18463".248. The expressions of Delaunay also lead to a theory, in which this coefficient is 18461".26. Each of these is to be multiplied by such a factor as shall reduce it to the value implicitly adopted in Hansen's tables. There Hansen adopts:—

$$I = 5^{\circ} 8' 39''.96$$

which is less by 8".04 than that of the theory. Ilence, from this alone would follow the correction:—

$$-8''.04 \sin (f + \omega).$$

But, the tables contain, among the perturbations, two terms which depend mainly on the same argument, namely:—

$$2''.705 \sin (f + \omega),$$

which, developed by putting $g + 2e \sin g$ for f, appears as a perturbation, and

$$3''.70 \sin (g + \omega),$$

which is attributed to the separation of the centers of figure and of gravity of the moon. The sum of the first two expressions being developed, become

- 5".319
$$\sin (g + \omega)$$

•+ 0".293 $\sin \omega$
- 0".292 $\sin (2g + \omega)$.

Adding the third, the term in $g + \omega$ will become

-
$$I''$$
.619 $\sin (g + \omega)$.

We are not concerned with the terms in ω and $2g + \omega$. The greater part of their amount may be considered as a *quasi* perturbation, due to the figure of the moon, and implicitly contained in the tables, but not belonging to the problem of three bodies.

With the last correction the term in $g + \omega$ becomes

18461".629
$$\sin (g + \omega)$$
,

which is the coefficient implicitly contained in Hansen's tables.

To this the writer found a correction of -0''.15 from Greenwich and Washington observations 1862-'74, but it will be retained without change. Hence all the coefficients in Hansen's β , as given in Table IV, are to be diminished by the factor

and those of Delaunay are to be increased by the factor

The terms in e and e' are to be modified by the same coefficients as in the case of the longitude. The only terms which will be appreciably affected by the change of e are those depending on ω and $2 g + \omega$.

The modifications here indicated have not been made in the results, because they are so slight, and affect so few terms, that each one can make them for himself.

The column Delaunay (1) contains, as before, the sum of the terms actually computed by Delaunay, and given by him in the Connaissances des Temps for 1869.

In column *Delaunay* (2) his coefficients are corrected by the higher terms, of which the value has been estimated by induction. Delaunay himself did not give these additions, so that they had to be estimated by the writer.

§ 5.

PARALLAX.

Hansen's theory gives the perturbations of the natural logarithm of the moon's radius vector, which are the negative of the perturbations of the logarithm sine parallax. The value of w, in seconds of arc, is found in the *Darlegung*, Part I, pages 409-411, and Part II, pages 224-226, 258, and 268. The moon's parallax p is given by Hansen under the form

$$\log \sin p = \log \frac{D(1 + e \cos f)}{a(1 - e^2)} - w,$$

in which D is the radius of the earth at the latitude of which the sine is $\sqrt{\frac{1}{3}}$, and a the moon's mean distance in the Hansenian theory, which is different in definition from the mean distance of the ordinary theories. It is not, however, necessary to reduce the one to the other directly, because they may be most satisfactorily compared by the values of the constant of parallax to which they lead.

Changing the logarithms to natural quantities and developing in powers of w, the above expression gives:—

$$\sin p = \frac{D}{a} \cdot \frac{1 + e \cos f}{1 - e^2} \left(1 - w + \frac{w^2}{2} - \text{etc.} \right)$$

and then

$$p = \sin p + \frac{\sin^3 p}{6} + \text{etc.}$$

In developing $e \cos f$ two methods of computation were used, as in the computation of the principal term of the latitude.

I. From CAYLEY's tables we have

$$\cos f = -e + \left(1 - \frac{9}{8}e^2 + \frac{25}{192}e^4\right)\cos z$$

$$+ \left(e - \frac{4}{3}e^3\right)\cos z z$$

$$+ \left(\frac{9}{8}e^2 - \frac{225}{128}e^4\right)\cos z z$$

$$+ \frac{4}{3}e^3\cos z z$$

$$+ \frac{625}{384}e^4\cos z z$$

and then by substituting $g + n \delta z$ for z we have $\cos f$ developed in multiples of g, etc

2. Putting

$$f = g + \delta f$$

we have

$$\cos f = \cos \delta f \cos g - \sin \delta f \sin g$$
.

The value of $\frac{D}{a}$ was derived by Hansen from the length of the seconds pendulum and the dimensions of the earth as found by Bessel. The derivation is given in the Astronomische Nachrichten, Volume XVII, page 300. The data made use of are:—

The result is

$$\log \frac{D}{a} = 8.2170139.$$

He gives as the resulting constant part of the sine of the parallax

and the changes in the constant produced by small changes in the data:-

The development subsequently given leads to a constant of

a result o".03 greater than that stated by Hansen.

In comparing the parallaxes of Hansen and Delaunay the only element which will materially affect the result is the constant of parallax: a comparison of the different values of this constant, which have been recently obtained, will therefore be of interest. Three distinct methods of obtaining this important element have been applied.

(α). The theoretical method founded on Kepler's, third law as expressed in the theory of gravitation, and derived fundamentally from the equation

$$a^3 n^2 \equiv m + M$$

a being the mean distance of the moon, which is immediately connected with the parallax; n the mean motion, of the value of which there is no doubt, and m and M the masses of the moon and earth, expressed in appropriate units, the determination of which is the most doubtful part of the problem.

- (β). Measures of the moon's position made at two distant stations, and reduced $t\theta$ a common moment.
- (γ) . Meridian declinations of the moon made at the same station, and reduced on the hypothesis that the undisturbed geocentric orbit is a great circle.

The last method is not well adapted to give a certain result, owing to the constant errors with which measures of absolute declinations are affected. We shall therefore confine our consideration to the first two.

Two determinations by method (α) , that of Hansen, just quoted, and that of Adams in the *Monthly Notices*, Vol. XIII, and the British *Nautical Almanac* for 1856, are available.

The data used by Mr. Adams are:—

^{*}This value in English feet was kindly communicated by Mr. Adams himself, not being explicitly quoted in his published paper.

The resulting value of the constant of the sine is given as 3422".325. To compare it with Hansen we have:—

Change in D = 0, - - - change of
$$\pi_0 = 0$$

" P = + 0^{m m}.046, " " - 0".05

" $\frac{1}{m} = + 1.5$, " " + 0".26

Applying the correction +0"21 to Hansen's constant, the result would be either 3422".27 or 3422".30, according as we accept Hansen's original constant or that deduced from the data of his lunar tables. The latter is probably the value to be preferred.

If we reduce the values both of Hansen and Adams to Hansen's data, according to the system already adopted, the results will be:—

The constant of reduction from the sine to the parallax itself is + 0".157.

β. The most recent determinations of the moon's parallax by measurement are those of Mr. Breen (Memoirs R. A. S. XXXII) and of Mr. Stone (Ibid. XXXIV). Both are founded on Cape observations and both lead to a constant of

It is not distinctly stated whether this is the constant of the parallax itself or of its sine. Mr. Breen's introduction (l. c. pp. 116, 117) seems to imply that he used Mr. Adams's expression for sine parallax as the parallax itself in reducing the Cape observations. But, in the reduction of the Greenwich observations, he applies Adams's correction to the parallax of Airy's lunar reductions, which gives the parallax itself. To put the matter into another shape: On p. 116 Mr. Breen has 3422".32 as the constant of parallax. On p. 132 he has a constant correction of o".68 to the Airy-Plana parallax, of which the constant is 3421".80, which gives 3422".48 as the constant of parallax.

We shall probably make a near approximation to the truth by assuming that Mr. Breen's mean provisional constant was 3422".40, and as he deduced a correction of + o".38 this would give us his result:—

Mr. Stone also finds a correction of +o''.38 to Mr. Adams's parallax. This would give:—

The evidence is therefore in favor of a positive correction to Hansen's constant; but, in accordance with the practice in other parts of this paper, the results as printed are all founded on Hansen's fundamental data.

In the Table V the columns contain-

- (1). The value of $\frac{D}{a}$. $\frac{1}{1-e^2}(1+e\cos f)$, expressed in seconds of arc.
- (2). The product of this quantity by $-w + \frac{w^2}{2}$
- (3). The coefficients for Hansen's sine parallax, formed by adding (1) and (2). If the parallax itself is required, it may be found by adding the reduction from the sine to the parallax itself, namely:—

+ 0".157 + 0".025 cos
$$g$$

+ 0".004 cos $(g - 2g^1 + 2\omega - 2\omega^1)$
+ 0".004 cos $(2g - 2g^1 + 2\omega 2\omega^1)$.

- (4). The coefficients of Delaunay's sine parallax, so far as actually computed by him. As he stopped at the terms of the fifth order, the hundredths of seconds are not always definitive.
- (5). The same, with the addition of quantities estimated by induction to represent the omitted terms of higher orders.
- (6) The corrections applied in the preceding column to obtain the most probable values of the coefficients.
 - (7). The deviation of Hansen's coefficients from the second set of Delaunay's.

As some of Delaunay's terms are doubtful from the insufficient convergence of his series, the coefficients of Adams's parallax, found in the *Monthly Notices R. A. S.*, Vol. XIII, p. 263, have been added for comparison. It will be seen that they agree closely with the coefficients of Hansen, though derived independently of them.

·				
	_		•	
		·		

NOTE.

The probability that the most accurate method of determining the solar parallax now available is that resting on the measurement of the velocity of light, has led to the acceptance of the following paper as one of the series having in view the increase of our knowledge of the celestial motions. The researches described in it, having been made at the United States Naval Academy, though at private expense, were reported to the Honorable Secretary of the Navy, and referred by him to this Office. At the suggestion of the writer, the paper was reconstructed with a fuller general discussion of the processes, and with the omission of some of the details of individual experiments.

To prevent a possible confusion of this determination of the velocity of light with another now in progress under official auspices, it may be stated that the credit and responsibility for the present paper rests with Master Michelson.

SIMON NEWCOMB,

Professor, U. S. Navy,

Superintendent Nautical Almanac.

EXPERIMENTAL DETERMINATION OF THE VELOCITY OF LIGHT.

BY ALBERT A. MICHELSON, Master, U. S. N.

INTRODUCTION.

In Cornu's elaborate memoir upon the determination of the velocity of light, several objections are made to the plan followed by Foucault, which will be considered in the latter part of this work. It may, however, be stated that the most important among these was that the deflection was too small to be measured with the required degree of accuracy. In order to employ this method, therefore, it was absolutely necessary that the deflection should be increased.

In November, 1877, a modification of Foucault's arrangement suggested itself, by which this result could be accomplished. Between this time and March of the following year a number of preliminary experiments were performed in order to familiarize myself with the optical arrangements. The first experiment tried with the revolving mirror produced a deflection considerably greater than that obtained by Foucault. Thus far the only apparatus used was such as could be adapted from the apparatus in the laboratory of the Naval Academy.

At the expense of \$10 a revolving mirror was made, which could execute 128 turns per second. The apparatus was installed in May, 1878, at the laboratory. The distance used was 500 feet, and the deflection was about twenty times that obtained by Foucault.*

These experiments, made with very crude apparatus and under great difficulties, gave the following table of results for the velocity of light in miles per second:

Mean 186500 ± 300 miles per second. or 300140 kilometers per second

^{*}See Proc. Am. Assoc. Adv. Science, Saint Louis meeting.

In the following July the sum of \$2,000 was placed at my disposal by a private gentleman for carrying out these experiments on a large scale. Before ordering any of the instruments, however, it was necessary to find whether or not it was practicable to use a large distance. With a distance (between the revolving and the fixed mirror) of 500 feet, in the preliminary experiments, the field of light in the eye-piece was somewhat limited, and there was considerable indistinctness in the image, due to atmospheric disturbances.

Accordingly, the same lens (39 feet focus) was employed, being placed, together with the other pieces of apparatus, along the north sea-wall of the Academy grounds, the distance being about 2,000 feet. The image of the slit, at noon, was so confused as not to be recognizable, but toward sunset it became clear and steady, and measurements were made of its position, which agreed within one one-hundredth of a millimeter. It was thus demonstrated that with this distance and a deflection of 100 millimeters this measurement could be made within the ten-thousandth part.

In order to obtain this deflection, it was sufficient to make the mirror revolve 250 times per second and to use a "radius" of about 30 feet. In order to use this large radius (distance from slit to revolving mirror), it was necessary that the mirror should be large and optically true; also, that the lens should be large and of great focal length. Accordingly the mirror was made 1½ inches in diameter, and a new lens, 8 inches in diameter, with a focal length of 150 feet was procured.

In January, 1879, an observation was taken, using the old lens, the mirror making 128 turns per second. The deflection was about 43 millimeters. The micrometer eye-piece used was substantially the same as Foucault's, except that part of the inclined plate of glass was silvered, thus securing a much greater quantity of light. The deflection having reached 43 millimeters, the inclined plate of glass could be dispensed with, the light going past the observer's head through the slit, and returning 43 millimeters to the left of the slit, where it could be easily observed.

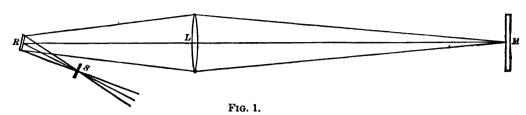

Thus the micrometer eye-piece is much simplified, and many possible sources of error are removed.

The field was quite limited, the diameter being, in fact, but little greater than the width of the slit. This would have proved a most serious objection to the new arrangement. With the new lens, however, this difficulty disappeared, the field being about twenty times the width of the slit. It was expected that, with the new lens, the image would be less distinct; but the difference, if any, was small, and was fully compensated by the greater size of the field.

The first observation with the new lens was made January 30, 1879. The deflection was 70 millimeters. The image was sufficiently bright to be observed without the slightest effort. The first observation with the new micrometer eye-piece was made April 2, the deflection being 115 millimeters.

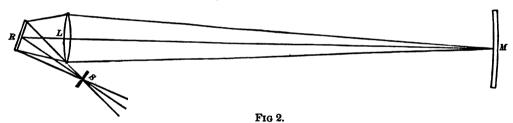

The first of the final series of observations was made on June 5. All the observations previous to this, thirty sets in all, were rejected. After this time, no set of observations nor any single observation was omitted.

THEORY OF NEW METHOD.

Let S, Fig. 1, be a slit, through which light passes, falling on R, a mirror free to rotate about an axis at right angles to the plane of the paper; L, a lens of great focal length, upon which the light falls which is reflected from R. Let M be a plane mirror whose surface is perpendicular to the line R, M, passing through the centers of R, L, and M, respectively. If L be so placed that an image of S is formed on the surface of M, then, this image acting as the object, its image will be formed at S, and will coincide, point for point, with S.

If, now, R be turned about the axis, so long as the light falls upon the lens, an image of the slit will still be formed on the surface of the mirror, though on a different part, and as long as the returning light falls on the lens an image of this image will be formed at S, notwithstanding the change of position of the first image at M. This result, namely, the production of a stationary image of an image in motion, is absolutely necessary in this method of experiment. It was first accomplished by Foucault, and in a manner differing apparently but little from the foregoing.

In his experiments L, Fig. 2, served simply to form the image of S at M, and M, the returning mirror, was spherical, the center coinciding with the axis of R. The lens L was placed as near as possible to R. The light forming the return image lasts, in this case, while the first image is sweeping over the face of the mirror, M. Hence, the greater the distance R M, the larger must be the mirror in order that the same amount of light may be preserved, and its dimensions would soon become inordinate. The difficulty was partly met by Foucault, by using five concave reflectors instead of one, but even then the greatest distance he found it practicable to use was only 20 meters.

Returning to Fig. 1, suppose that R is in the principal focus of the lens L; then, if the plane mirror M have the same diameter as the lens, the first, or moving image, will remain upon M as long as the axis of the pencil of light remains on the lens, and this will be the case no matter what the distance may be.

When the rotation of the mirror R becomes sufficiently rapid, then the flashes of light which produce the second or stationary image become blended, so that the image appears to be continuous. But now it no longer coincides with the slit, but is deflected in the direction of rotation, and through twice the angular distance described by the

mirror, during the time required for light to travel twice the distance between the mirrors. This displacement is measured by the tangent of the arc it subtends. To make this as large as possible, the distance between the mirrors, the radius, and the speed of rotation should be made as great as possible.

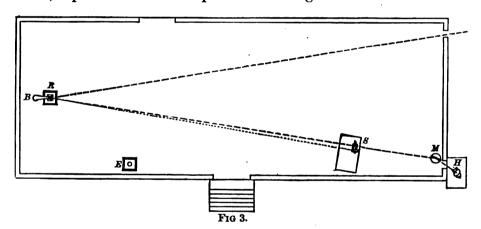

The second condition conflicts with the first, for the radius is the difference be tween the focal length for parallel rays, and that for rays at the distance of the fixed mirror. The greater the distance, therefore, the smaller will be the radius.

There are two ways of solving the difficulty: first, by using a lens of great focal length; and secondly, by placing the revolving mirror within the principal focus of the lens. Both means were employed. The focal length of the lens was 150 feet, and the mirror was placed about 15 feet within the principal focus. A limit is soon reached, however, for the quantity of light received diminishes very rapidly as the revolving mirror approaches the lens.

ARRANGEMENT AND DESCRIPTION OF APPARATUS.

SITE AND PLAN.

The site selected for the experiments was a clear, almost level, stretch along the north sea-wall of the Naval Academy. A frame building was erected at the western end of the line, a plan of which is represented in Fig. 3.

The building was 45 feet long and 14 feet wide, and raised so that the line along which the light traveled was about 11 feet above the ground. A heliostat at H reflected the sun's rays through the slit at S to the revolving mirror R, thence through a hole in the shutter, through the lens, and to the distant mirror.

THE HELIOSTAT.

The heliostat was one kindly furnished by Dr. Woodward, of the Army Medical Museum, and was a modification of Foucault's form, designed by Keith. It was found to be accurate and easy to adjust. The light was reflected from the heliostat to a plane mirror, M, Fig. 3, so that the former need not be disturbed after being once adjusted.

THE REVOLVING MIRROR.

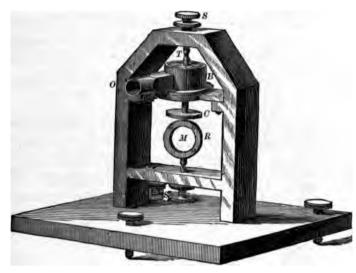

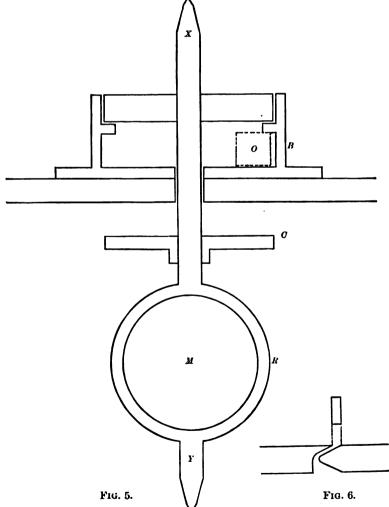

Fig. 4.

The revolving mirror was made by Fauth & Co., of Washington. It consists of a cast-iron frame resting on three leveling screws, one of which was connected by cords to the table at S, Fig. 3, so that the mirror could be inclined forward or backward while making the observations.

Two binding screws, S, S, Fig. 4, terminating in hardened steel conical sockets, hold the revolving part. This consists of a steel axle, X, Y, Figs. 4 and 5, the pivots being conical and hardened. The axle

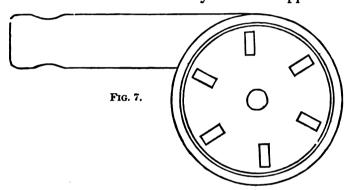

expands into a ring at R, which holds the mirror M. The latter was a disc of plane glass, made by Alvan Clark & Sons, about 1½ inch in diameter and 0.2 inch thick. It was silvered on one side only, the reflection taking place from the outer or front surface. A species of turbine wheel, T, is held on the axle by friction. This wheel has six openings for the escape of air; a section of one of them is represented in Fig 6.

ADJUSTMENT OF THE REVOLV-ING MIRROR.

The air entering on one side at O, Fig. 5, acquires a rotary motion in the box B, B, carrying the wheel with it, and this motion is assisted by the reaction of the air in escaping. The disc C serves the purpose of bringing the center of gravity in the axis

of rotation. This was done, following Foucault's plan, by allowing the pivots to rest on two inclined planes of glass, allowing the arrangement to come to rest, and filing away the lowest part of the disc; trying again, and so on, till it would rest in indifferent equilibrium. The part corresponding to C, in Foucault's apparatus, was furnished with three vertical screws, by moving which the axis of figure was brought into coincidence with the axis of rotation. This adjustment was very troublesome. Fortunately, in this apparatus it was found to be unnecessary.

When the adjustment is perfect the apparatus revolves without giving any sound, and when this is accomplished, the motion is regular and the speed great. A slight deviation causes a sound due to the rattling of the pivots in the sockets, the speed is very much diminished, and the pivots begin to wear. In Foucault's apparatus oil was furnished to the pivots, through small holes running through the screws, by pressure of a column of mercury. In this apparatus it was found sufficient to touch the

pivots occasionally with a drop of oil.

Fig. 7 is a view of the turbine, box, and supply-tube, from above. The quantity of air entering could be regulated by a valve to which was attached a cord leading to the observer's table.

The instrument was mounted on a brick pier.

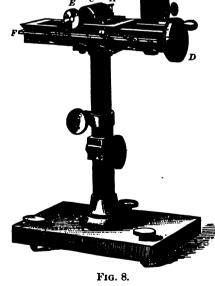

THE MICROMETER.

This instrument is shown in perspective in Fig. 8, and in plan by Fig. 9. The adjustable slit S is clamped to the frame F. A long millimeter-screw, not shown in Fig. 8, terminating in the divided head D, moves the carriage C, which supports the eye-piece E. The frame is furnished with a brass scale at F for counting revolutions, the head counting hundredths. The eye-piece consists of a single achromatic lens, whose focal length is about two inches At its focus, in H, and in nearly the same plane as the face of the slit, is a single vertical silk fiber. The apparatus is furnished with a standard with rack and pinion, and the base furnished with leveling screws.

In measuring the deflection, the eye-piece is moved till the cross-hair bisects the slit, and the reading of the scale and divided head gives the position. This measurement need not be repeated unless the position or width of the slit is changed. Then

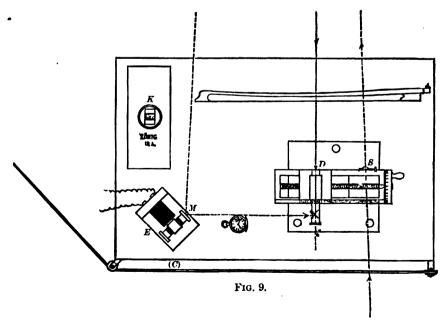

the eye-piece is moved till the cross-hair bisects the deflected image of the slit; the reading of scale and head are again taken, and the difference in readings gives the deflection. The screw was found to have no lost motion, so that readings could be taken with the screw turned in either direction.

MEASUREMENT OF SPEED OF ROTATION.

To measure the speed of rotation, a tuning-fork, bearing on one prong a steel mirror, was used. This was kept in vibration by a current of electricity from five "gravity" cells. The fork was so placed that the light from the revolving mirror was reflected to a piece of plane glass, in front of the lens of the eye-piece of the micrometer, inclined at an angle of 45°, and thence to the eye. When fork and revolving mirror are both at rest, an image of the revolving mirror is seen. When the fork vibrates, this image is drawn out into a band of light.

When the mirror commences to revolve, this band breaks up into a number of moving images of the mirror; and when, finally, the mirror makes as many turns as the fork makes vibrations, these images are reduced to one, which is stationary. This is also the case when the number of turns is a submultiple. When it is a multiple or simple ratio, the only difference is that there are more images. Hence, to make the mirror execute a certain number of turns, it is simply necessary to pull the cord attached to the valve to the right or left till the images of the revolving mirror come to rest.

The electric fork made about 128 vibrations per second. No dependence was placed upon this rate, however, but at each set of observations it is compared with a standard Ut₃ fork, the temperature being noted at the same time. In making the comparison the sound-beats produced by the forks were counted for 60 seconds. It is interesting to note that the electric fork, as long as it remained untouched and at the same temperature, did not change its rate more than one or two hundredths vibrations per second.

THE OBSERVER'S TABLE.

Fig. 9 represents the table at which the observer sits. The light from the heliostat passes through the slit at S, goes to the revolving mirror, &c., and, on its return, forms an image of the slit at D, which is observed through the eye-piece. E represents the electric fork (the prongs being vertical) bearing the steel mirror M. K is the standard fork on its resonator. C is the cord attached to the valve supplying air to the turbine.

THE LENS.

The lens was made by Alvan Clark & Sons. It was 8 inches in diameter; focal length, 150 feet; not achromatic. It was mounted in a wooden frame, which was placed on a support moving on a slide, about 16 feet long, placed about 80 feet from the building. As the diameter of the lens was so small in comparison with its focal length, its want of achromatism was inappreciable. For the same reason, the effect of "parallax" (due to want of coincidence in the plane of the image with that of the silk fiber in the eye-piece) was too small to be noticed.

THE FIXED MIRROR.

The fixed mirror was one of those used in taking photographs of the transit of Venus. It was about 7 inches in diameter, mounted in a brass frame capable of adjustment in a vertical and a horizontal plane by screw motion. Being wedge-shaped, it had to be silvered on the front surface. To facilitate adjustment, a small telescope furnished with cross-hairs was attached to the mirror by a universal joint. The heavy frame was mounted on a brick pier, and the whole surrounded by a wooden case to protect it from the sun.

ADJUSTMENT OF THE FIXED MIRROR.

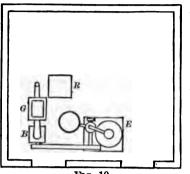

The adjustment was effected as follows: A theodolite was placed at about 100 feet in front of the mirror, and the latter was moved about by the screws till the observer at the theodolite saw the image of his telescope reflected in the center of the mirror. Then the telescope attached to the mirror was pointed (without moving the mirror itself) at a mark on a piece of card-board attached to the theodolite. Thus the line of collimation of the telescope was placed at right angles to the surface of the mirror. The theodolite was then moved to 1,000 feet, and, if found necessary, the adjustment was repeated. Then the mirror was moved by the screws till its telescope pointed at the hole in the shutter of the building. The adjustment was completed by moving the mirror, by signals, till the observer, looking through the hole in the shutter, through a good spy-glass, saw the image of the spy-glass reflected centrally in the mirror.

The whole operation was completed in a little over an hour.

Notwithstanding the wooden case about the pier, the mirror would change its position between morning and evening; so that the last adjustment had to be repeated before every series of experiments.

APPARATUS FOR SUPPLYING AND REGULATING THE BLAST OF AIR.

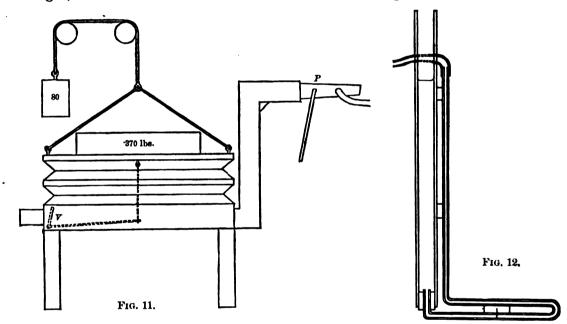

Fig. 10 represents a plan of the lower floor of the building. E is a three-horse

power Lovegrove engine and boiler, resting on a stone foundation; B, a small Roots' blower; G, an automatic regulator. From this the air goes to a delivery-pipe, up through the floor, and to the turbine. The engine made about 4 turns per second and the blower about 15. At this speed the pressure of the air was about half a pound per square inch.

The regulator, Fig. 11, consists of a strong bellows supporting a weight of 370 pounds, partly counterpoised by 80 pounds in order to prevent the bellows from sagging. When the pressure of air from the blower exceeds

the weight, the bellows commences to rise, and, in so doing, closes the valve V.

This arrangement was found in practice to be insufficient, and the following addition was made: A valve was placed at P, and the pipe was tapped a little farther on, and a rubber tube led to a water-gauge, Fig 12. The column of water in the smaller tube is depressed, and, when it reaches the horizontal part of the tube, the slightest variation of pressure sends the column from one end to the other. This is checked by an assistant at the valve; so that the column of water is kept at about the same place, and the pressure thus rendered very nearly constant. The result was satisfactory, though not in the degree anticipated. It was possible to keep the mirror at a constant speed for three or four seconds at a time, and this was sufficient for an observation. Still it would have been more convenient to keep it so for a longer time.

I am inclined to think that the variations were due to changes in the friction of the pivots rather than to changes of pressure of the blast of air.

It may be mentioned that the test of uniformity was very delicate, as a change of speed of one or two hundredths of a turn per second could easily be detected.

METHOD FOLLOWED IN EXPERIMENT.

It was found that the only time during the day when the atmosphere was sufficiently quiet to get a distinct image was during the hour after sunrise, or during the hour before sunset. At other times the image was "boiling" so as not to be recognizable. In one experiment the electric light was used at night, but the image was no more distinct than at sunset, and the light was not steady.

The method followed in experiment was as follows: The fire was started half an hour before, and by the time everything was ready the gauge would show 40 or 50 pounds of steam. The mirror was adjusted by signals, as before described. The heliostat was placed and adjusted. The revolving mirror was inclined to the right or left, so that the *direct* reflection of light from the slit, which otherwise would flash into the eye-piece at every revolution, fell either above or below the eye-piece.*

The revolving mirror was then adjusted by being moved about, and inclined forward and backward, till the light was seen reflected back from the distant mirror. This light was easily seen through the coat of silver on the mirror.

The distance between the front face of the revolving mirror and the cross-hair of the eye-piece was then measured by stretching from the one to the other a steel tape, making the drop of the catenary about an inch, as then the error caused by the stretch of the tape and that due to the curve just counterbalance each other.

The position of the slit, if not determined before, was then found as before described. The electric fork was started, the temperature noted, and the sound-beats between it and the standard fork counted for 60 seconds. This was repeated two or three times before every set of observations.

The eye-piece of the micrometer was then set approximately † and the revolving mirror started. If the image did not appear, the mirror was inclined forward or backward till it came in sight.

The cord connected with the valve was pulled right or left till the images of the revolving mirror, represented by the two bright round spots to the left of the cross-hair, came to rest. Then the screw was turned till the cross-hair bisected the deflected image of the slit. This was repeated

till ten observations were taken, when the mirror was stopped, temperature noted, and beats counted. This was called a set of observations. Usually five such sets were taken morning and evening.

Fig. 13 represents the appearance of the image of the slit as seen in the eye-piece magnified about five times.

^{*}Otherwise this light would overpower that which forms the image to be observed. As far as I am aware, Foucault does not speak of this difficulty. If he allowed this light to interfere with the brightness of the image, he neglected a most obvious advantage. If he did incline the axis of the mirror to the right or left, he makes no allowance for the error thus introduced.

[†]The deflection being measured by its tangent, it was necessary that the scale should be at right angles to the radius (the radius drawn from the mirror to one or the other end of that part of the scale which represents this tangent). This was done by setting the eye-piece approximately to the expected deflection, and turning the whole micrometer about a vertical axis till the cross-hair bisected the circular field of light reflected from the revolving mirror. The axis of the eye-piece being at right angles to the scale, the latter would be at right angles to radius drawn to the cross-hair.

DETERMINATION OF THE CONSTANTS.

COMPARISON OF THE STEEL TAPE WITH THE STANDARD YARD.

The steel tape used was one of Chesterman's, 100 feet long. It was compared with Wurdeman's copy of the standard yard, as follows:

Temperature was 55° Fahr.

The standard yard was brought under the microscopes of the comparator; the cross-hair of the unmarked microscope was made to bisect the division marked o, and the cross-hair of the microscope, marked I, was made to bisect the division marked 36. The reading of microscope I was taken, and the other microscope was not touched during the experiment. The standard was then removed and the steel tape brought under the microscopes and moved along till the division marked o.1 (feet) was bisected by the cross-hair of the unmarked microscope. The screw of microscope I was then turned till its cross-hair bisected the division marked 3.1 (feet), and the reading of the screw taken. The difference between the original reading and that of each measurement was noted, care being taken to regard the direction in which the screw was turned, and this gave the difference in length between the standard and each succesive portion of the steel tape in terms of turns of the micrometer-screw.

To find the value of one turn, the cross-hair was moved over a millimeter scale, and the following were the values obtained:

Turns of screw of microscope I in 1 mm —

7.68	7.73	7.60	7.67
7.68	7.62	7.65	7.57
7.72	7.70	7.64	₋ 7.69
7.65	7.59	7.63	7.64
7.55	7.65	7.61	7.63
	Mean	= 7.65	
	TT 4	m m	

Hence one turn $\equiv 0.1307^{mm}$. or $\equiv 0.0051$ inch.

The length of the steel tape from 0.1 to 99.1 was found to be greater than 33 yards, by 7.4 turns = .96 mm - +.003 feet.

Correction for temperature - - - - +.003 feet.

Length - - - - - - - - - - 100.000 feet.

Corrected length - - - - 100.006 feet.

DETERMINATION OF THE VALUE OF MICROMETER.

Two pairs of lines were scratched on one slide of the slit, about 38 mm apart, i. e., from the center of first pair to center of second pair. This distance was measured at intervals of 1mm through the whole length of the screw, by bisecting the interval between each two pairs by the vertical silk fiber at the end of the eye-piece. With these values a curve was constructed which gave the following values for this distance, which we shall call D:

, 0110		2,.										_

140 turns -
                                                 38.130
```

On comparing the scale with the standard meter, the temperature being 16°.5 °C., 140 divisions were found to $= 139.462^{\text{mm}}$. This multiplied by $(1 + .0000188 \times 16.5) =$ 139.505 mm.

One hundred and forty divisions were found to be equal to 140.022 turns of the screw, whence 140 turns of the screw = 139 483 mm, or 1 turn of the screw = 0.996305 mm.

This is the average value of one turn in 140.

But the average value of D, for 140 turns is, from the preceding table, 38.130.

Therefore, the true value of D, is $38.130 \times .996305^{mm}$, and the average value of one turn for 10, 20, 30, etc., turns, is found by dividing $38.130 \times .996305$ by the values of D, given in the table.

This gives the value of a turn-

										mm.
For the first	10 turns	-	-	-	-	-		-	-	0.99570
	20 turns	-	-	-	-	-	-	-	-	0 99570

•	140 turns	-	-	-	-	-	-	-	-	0.99630

Note.—The micrometer has been sent to Professor Mayer, of Hoboken, to test the screw again, and to find its value. The steel tape has been sent to Professor Rogers, of Cambridge, to find its length again. (See page 145.)

MEASUREMENT OF THE DISTANCE BETWEEN THE MIRRORS.

Square lead weights were placed along the line, and measurements taken from the forward side of one to forward side of the next. The tape rested on the ground (which was very nearly level), and was stretched by a constant force of 10 pounds.

The correction for length of the tape (100.006) was + 0.12 of a foot.

To correct for the stretch of the tape, the latter was stretched with a force of 15 pounds, and the stretch at intervals of 20 feet measured by a millimeter scale

									mm.
At 100 feet the stretch was	-	-	-	-	-	-	-	-	8. o
80 feet the stretch was	-	-	-	-	-	-	· -	-	5.0
60 feet the stretch was	-	-	-	-	-	-	-	-	5 O
40 feet the stretch was	-	-	-	-	-	-	-	-	3.5
20 feet the stretch was	-	-	-	-	-	-	-	-	1.5
									
200									22.00

```
Weighted mean = 7.7<sup>mm</sup>.

For 10 pounds, stretch = 5.1<sup>mm</sup>.

= 0.0167 feet.

Correction for whole distance = + 0.33 feet.
```

The following are the values obtained from five separate measurements of the distance between the caps of the piers supporting the revolving mirror and the distant reflector; allowance made in each case for effect of temperature:

```
1985 13 feet.
1985.17 feet.
1984.93 feet.
1985.09 feet.
1985.09 feet.
```

Mean = 1985.082 feet.

+.70. Cap of pier to revolving mirror.

+.33. Correction for stretch of tape.

+.12. Correction for length of tape.

1986.23. True distance between mirrors.

RATE OF STANDARD Ut, FORK.

The rate of the standard Ut, fork was found at the Naval-Academy, but as so much depended on its accuracy, another series of determinations of its rate was made, together with Professor Mayer, at the Hoboken Institute of Technology.

Set of determinations made at Naval Academy.

The fork was armed with a tip of copper foil, which was lost during the experiments and replaced by one of platinum having the same weight, 4.6 mgr. The fork, on its resonator, was placed horizontally, the platinum tip just touching the lamp-blacked cylinder of a Schultze chronoscope. The time was given either by a sidereal break-circuit chronometer or by the break-circuit pendulum of a mean-time clock. In the former case the break-circuit worked a relay which interrupted the current from three Grove cells. The spark from the secondary coil of an inductorium was delivered from a wire near the tip of the fork. Frequently two sparks near together were given, in which case the first alone was used. The rate of the chronometer, the record of which was kept at the Observatory, was very regular, and was found by observations of transits of stars during the week to be + 1.3 seconds per day, which is the same as the recorded rate.

SPECIMEN OF A DETERMINATION OF RATE OF Ut, FORK.

Temp. $\equiv 27^{\circ}$ C. Column 1 gives the number of the spark or the number of the second. Column 2 gives the number of sinuosities or vibrations at the corresponding second. Column 3 gives the difference between 1 and 11, 2 and 12, 3 and 13, etc.

The correction for temperature was found by Professor Mayer by counting the sound-beats between the standard and another Ut, fork, at different temperatures. His result is +.012 vibrations per second for a diminution of 1° Fahr. Using the same method, I arrived at the result +.0125. Adopted +.012.

Résumé of determinations made at Naval Academy.

In the following table the first column gives the date, the second gives the total number of seconds, the third gives the result uncorrected for temperature, the fourth gives the temperature (centigrade), the fifth gives the final result, and the sixth the difference between the greatest and least values obtained in the several determinations for intervals of ten seconds:

				Mean =	256.072	
;	8	20	255.887	26.6	256.066	0.03
	8	20	255.905	26.6	256.084	0.06

July .	4	20	255.882	27.0	256.069	0.07

In one of the preceding experiments, I compared the two Vt₃ forks while the standard was tracing its record on the cylinder, and also when it was in position as for use in the observations. The difference, if any, was less than .o. vibration per second.

Second determination.

(Joint work with Professor A. M. Mayer, Stevens Institute, Hoboken.)

The fork was wedged into a wooden support, and the platinum tip allowed to rest on lampblacked paper, wound about a metal cylinder, which was rotated by hand Time was given by a break-circuit clock, the rate of which was ascertained, by comparisons with Western Union time-ball, to be 9.87 seconds. The spark from secondary coil of the inductorium passed from the platinum tip, piercing the paper. The size of the spark was regulated by resistances in primary circuit.

The following is a specimen determination:

Column 1 gives the number of the spark or the number of seconds. Column 2 gives the corresponding number of sinuosities or vibrations. Column 3 gives the difference between the 1st and 7th \div 6, 2nd and 8th \div 6, etc.

Mean = 256.094

EFFECT OF SUPPORT AND OF SCRAPING.

The standard Vt₃ fork held in its wooden support was compared with another fork on a resonator loaded with wax and making with standard about five beats per second. The standard was free from the cylinder. The beats were counted by coincidences with the ½ second beats of a watch.

Specimen.

Coincidences were marked—

```
At 32 seconds.

37 seconds.

43.5 seconds.

49 seconds.

54.5 seconds.

61.5 seconds.

61.5 - 32 = 29.5.

29.5 ÷ 5 = 5.9 = time of one interval.
```

Résumé.

I	-	-	-	-	5.9
2	-	-	-	-	6.2
3	-	-	-	-	6.2
4	-	-	-	-	6.2

Mean \pm 6.13 \pm time of one interval between coincidences.

In this time the watch makes $6.13 \times 5 = 30.65$ beats, and the forks make 30.65 + 1 = 31.65 beats.

Hence the number of beats per second is $31.65 \div 6.13 = 5.163$.

Specimen.

Circumstances the same as in last case, except that standard Vt₃ fork was allowed to trace its record on the lampblacked paper, as in finding its rate of vibration.

Coincidences were marked at—

```
59 seconds.

04 seconds.

10.5 seconds.

17 seconds.

77 - 59 = 18.

18 \div 3 = 6.0 = time of one interval.
```

Résumé.

No. 1	-	-	-	6.0	seconds

Note —The result of first determination excludes all work except the series commencing July 4. If previous work is included, and also the result first obtained by Professor Mayer, the result would be 256.089.

The previous work was omitted on account of various inaccuracies and want of practice, which made the separate results differ widely from each other.

THE FORMULÆ.

The formulæ employed are—

(1)
$$\tan \varphi = \frac{d_r}{r}$$

(2) $V = \frac{2592000'' \times D \times n}{\varphi''}$

 $\varphi =$ angle of deflection.

 $d_{i} =$ corrected displacement (linear).

r =radius of measurement.

D = twice the distance between the mirrors.

n = number of revolutions per second.

 $\alpha =$ inclination of plane of rotation.

d = deflection as read from micrometer.

B = number of beats per second between electric Vt2 fork and standard Vt3

Cor = correction for temperature of standard Vt₃.

V = velocity of light.

T = value of one turn of screw (Table, page 126.)

Substituting for d, its value or $d \times T \times \sec \alpha$ (log sec $\alpha = .00008$), and for D its value 3972.46, and reducing to kilometers, the formulæ become—

(3)
$$\tan \varphi = c_1 \frac{dT}{r}$$
; $\log c_1 = .51607$

(4)
$$V = c \frac{n}{\varphi}$$
; $\log c = .49670$

D and r are expressed in feet and d_r in millimeters.

Vt. fork makes 256.070 vibrations per second at 65° Fahr.

D = 3972.46 feet.

 $\tan \alpha = \text{tangent of angle of inclination of plane of rotation} = 0.02$ in all but the last twelve observations, in which it was 0.015.

 $\log c_1 = .51607$ (.51603 in last twelve observations.).

 $\log c = .49670.$

The electric fork makes $\frac{1}{2}$ (256.070 + B + cor.) vibrations per second, and n is a multiple, submultiple, or simple ratio of this.

OBSERVATIONS.

SPECIMEN OBSERVATION.

June 17. sunset. Image good; best in column (4).

The columns are sets of readings of the micrometer for the deflected image of slit.

In the following table, the numbers in the column headed "Distinctness of Image" are thus translated: 3, good; 2, fair; 1, poor. These numbers do not, however, show the relative weights of the observations

The numbers contained in the columns headed "Position of Deflected Image," "Position of Slit," and displacement of image in divisions were obtained as described in the paragraph headed "Micrometer," page 120.

The column headed "B" contains the number of "beats" per second between the electric Vt₂ fork and the standard Vt₃ as explained in the paragraph headed "Measurement of the Speed of Rotation." The column headed "Cor." contains the correction of the rate of the standard fork for the difference in temperature of experiment and 65° Fahr., for which temperature the rate was found. The numbers in the column headed "Number of revolutions per second" were found by applying the corrections in the two preceding columns to the rate of the standard, as explained in the same paragraph.

The "radius of measurement" is the distance between the front face of the revolving mirror and the cross-hair of the micrometer.

The numbers in the column headed "Value of one turn of the screw" were taken from the table, page 127.

In the last two sets of June 13, the micrometer was fixed at 113.41 and 112.14 respectively. The image was bisected by the cross-hair, and kept as nearly as possible in this place, meantime counting the number of seconds required for the image of the revolving mirror to complete 60 oscillations. In other words, instead of measuring the deflection, the speed of rotation was measured. In column 7 for these two sets, the numbers 11 and 6 are the differences between the greatest and the smallest number of seconds observed.

In finding the mean value of V from the table, the sets are all given the same weight. The difference between the result thus obtained and that from any system of weights is small, and may be neglected.

The following table gives the result of different groupings of sets of observations. Necessarily some of the groups include others:

DISCUSSION OF ERRORS.

The value of V depends on three quantities D, n, and φ . These will now be considered in detail.

THE DISTANCE.

The distance between the two mirrors may be in error, either by an erroneous determination of the length of the steel tape used, or by a mistake in the measurement of the distance by the tape.

The first may be caused by an error in the copy of the standard yard, or in the comparison between the standard and the tape. An error in this copy, of .00036 inch, which, for such a copy, would be considered large, would produce an error of only .00001 in the final result. Supposing that the bisections of the divisions are correct to .0005 inch, which is a liberal estimate, the error caused by supposing the error in each yard to be in the same direction would be only .000014; or the total error of the tape, if both errors were in the same direction, would be .000024 of the whole length.

The calculated probable error of the five measurements of the distance was ± .000015; hence the total error due to D would be at most .00004. The tape has been sent to Professor Rogers, of Cambridge, for comparison, to confirm the result.

THE SPEED OF ROTATION.

This quantity depends on three conditions It is affected, first, by an error in the rate of the standard; second, by an error in the count of the sound beats between the forks; and third, by a false estimate of the moment when the image of the revolving mirror is at rest, at which moment the deflection is measured.

The calculated probable error of the rate is .000016. If this rate should be questioned, the fork can be again rated and a simple correction applied. The fork is carefully kept at the Stevens Institute, Hoboken, and comparisons were made with two other forks, in case it was lost or injured.

In counting the sound beats, experiments were tried to find if the vibrations of the standard were affected by the other fork, but no such effect could be detected. In each case the number of beats was counted correctly to .o2, or less than .ooo1 part, and in the great number of comparisons made this source of error could be neglected.

The error due to an incorrect estimate of the exact time when the images of the revolving mirror came to rest was eliminated by making the measurement sometimes when the speed was slowly increasing, and sometimes when slowly decreasing. Further, this error would form part of the probable error deduced from the results of observations.

We may then conclude that the error, in the measurement of n, was less than .00002.

THE DEFLECTION.

The angle of deflection φ was measured by its tangent, $\tan \varphi = \frac{d}{r}$; d was measured by the steel screw and brass scale, and r by the steel tape.

The value of one turn of the screw was found by comparison with the standard meter for all parts of the screw. This measurement, including the possible error of the copy of the standard meter, I estimate to be correct to .00005 part. The instrument is at the Stevens Institute, where it is to be compared with a millimeter scale made by Professor Rogers, of Cambridge.

The deflection was read to within three or four hundredths of a turn at each observation, and this error appears in the probable error of the result.

The deflection is also affected by the inclination of the plane of rotation to the horizon. This inclination was small, and its secant varies slowly, so that any slight error in this angle would not appreciably affect the result.

The measurement of r is affected in the same way as D, so that we may call the greatest error of this measurement .00004. It would probably be less than this, as the mistakes in the individual measurements would also appear in the probable error of the result.

The measurement of φ was not corrected for temperature. As the corrections would be small they may be applied to the final result. For an increase of 1° F, the correction to be applied to the screw for unit length would be -.000066. The correction for the brass scale would be +.0000105, or the whole correction for the micrometer would be +.000004. The correction for the steel tape used to measure r would be +.000066. Hence the correction for tan. φ would be -.000003 t. The average temperature of the experiments is $75^{\circ}.6$ F. 75.6-62.5=13.1. $-.000003 \times 13.1=-.00004$

Hence φ should be divided by 1.00004, or the final result should be multiplied by 1.00004 This would correspond to a correction of + 12 kilometers.

The greatest error, excluding the one just mentioned, would probably be less than .00009 in the measurement of φ .

Summing up the various errors, we find, then, that the total constant error, in the most unfavorable case, where the errors are all in the same direction, would be .00015. Adding to this the probable error of the result, .0002, we have for the limiting value of the error of the final result \pm .00017. This corresponds to an error of \pm 51 kilometers.

The correction for the velocity of light in vacuo is found by multiplying the speed in air by the index of refraction of air, at the temperature of the experiments. The error due to neglecting the barometric height is exceedingly small. This correction, in kilometers, is +80.

OBJECTIONS CONSIDERED.

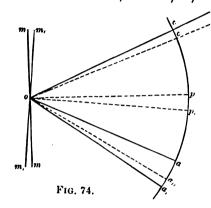

MEASUREMENT OF THE DEFLECTION.

The chief objection, namely, that in the method of the revolving mirror the deflection is small, has already been sufficiently answered. The same objection, in another form, is that the image is more or less indistinct. This is answered by a glance at the tables. These show that in each individual observation the average error was only three ten-thousandths of the whole deflection.

UNCERTAINTY OF LAWS OF REFLECTION AND REFRACTION IN MEDIA IN RAPID ROTATION.

What is probably hinted at under the above heading is that there may be a possibility that the rapid rotation of the mirror throws the reflected pencil in the direction of rotation. Granting that this is the case, an inspection of Fig. 14 shows that the deflection will not be affected.

In this figure let m m be the position of the mirror when the light first falls on it from the slit at a, and m, m, the position when the light returns.

From the axis o draw op op, perpendicular to mm and to m, m, respectively. Then, supposing there is no such effect, the course of the axis of the pencil of light would be $a \circ c$ mirror $c \circ a$. That is, the angle of deflection would be $a \circ a$, double the angle $p \circ p$. If now the mirror be supposed to carry the pencil with it, let $o \circ c$, be the direction of the pencil on leaving the mirror mm; i. e., the motion of the mirror has changed the direction of the reflected ray through the angle $c \circ c$. The course would then be $a \circ c$, mirror c, o. From o the reflection would take place in the direction a, making

the angles c, o p, and p, o a,, equal. But the angle c o c, must be added to p o a,, in consequence of the motion of the mirror, or the angle of deviation will be a o a,, + c o c, = a. (1)

By construction—

$$c \circ p, \equiv p, o a, \quad (2)$$

$$c, o p, \equiv p, o a, \quad (3)$$

Subtracting (3) from (2) we have— $c \circ p, -c, \circ p, \equiv p, \circ a, -p' \circ a,, \text{ or}$

Or the deflection has remained unaltered.

RETARDATION CAUSED BY REFLECTION.

Cornu, in answering the objection that there may be an unknown retardation by reflection from the distant mirror, says that if such existed the error it would introduce in his own work would be only $\frac{1}{7000}$ that of Foucault, on account of the great distance used, and on account of there being in his own experiments but one reflection instead of twelve.

In my own experiments the same reasoning shows that if this possible error made a difference of 1 per cent in Foucault's work (and his result is correct within that amount), then the error would be but .00003 part.

DISTORTION OF THE REVOLVING MIRROR.

It has been suggested that the distortion of the revolving mirror, either by twisting or by the effect of centrifugal force, might cause an error in the deflection.

The only plane in which the deflection might be affected is the plane of rotation. Distortions in a vertical plane would have simply the effect of raising, lowering, or extending the slit.

Again, if the mean surface is plane there will be no effect on the deflection, but simply a blurring of the image.

Even if there be a distortion of any kind, there would be no effect on the deflection if the rays returned to the same portion whence they were reflected.

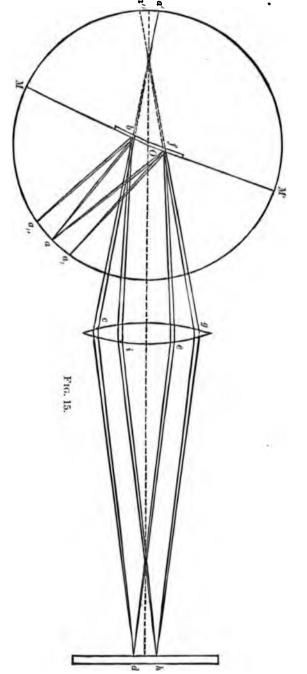

The only case which remains to be considered, then, is that given in Fig. 15, where the light from the slit a, falls upon a distorted mirror, and the return light upon a different portion of the same.

The one pencil takes the course abcd efa_n , while the other follows the path $afghiba_n$.

In other words, besides the image coinciding with a, there would be two images, one on either side of a, and in case there were more than two portions having different inclinations there would be formed as many images to correspond. If the surfaces are not plane, the only effect is to produce a distortion of the image.

As no multiplication of images was observed, and no distortion of the one image, it follows that the distortion of the mirror was too small to be noticed, and that even if it were larger it could not affect the deflection.

The figure represents the distorted mirror at rest, but the reasoning is the

same when it is in motion, save that all the images will be deflected in the direction of rotation.

IMPERFECTION OF THE LENS.

It has also been suggested that, as the pencil goes through one-half of the lens and returns through the opposite half, if these two halves were not exactly similar,

the return image would not coincide with the slit when the mirror was at rest. This would undoubtedly be true if we consider but one-half of the original pencil. It is evident, however, that the other half would pursue the contrary course, forming another image which falls on the other side of the slit, and that both these images would come into view, and the line midway between them would coincide with the true position. No such effect was observed, and would be very unlikely to occur. If the lens was imperfect, the faults would be all over the surface, and this would produce simply an indistinctness of the image.

Moreover, in the latter part of the observations the mirror was inverted, thus producing a positive rotation, whereas the rotation in the preceding sets was negative. This would correct the error mentioned if it existed, and shows also that no constant errors were introduced by having the rotation constantly in the same direction, the results in both cases being almost exactly the same.

PERIODIC VARIATIONS IN FRICTION.

If the speed of rotation varied in the same manner in each revolution of the mirror, the chances would be that, at the particular time when the reflection took place, the speed would not be the same as the average speed found by the calculation. Such a periodic variation could only be caused by the influence of the frame or the pivots. For instance, the frame would be closer to the ring which holds the mirror twice in every revolution than at other times, and it would be more difficult for the mirror to turn here than at a position 90° from this. Or else there might be a certain position, due to want of trueness of shape of the sockets, which would cause a variation of friction at certain parts of the revolution.

To ascertain if there were any such variations, the position of the frame was changed in azimuth in several experiments. The results were unchanged showing that any such variation was too small to affect the result.

CHANGE OF SPEED OF ROTATION.

In the last four sets of observations the speed was lowered from 256 turns to 192, 128, 96, and 64 turns per second. The results with these speeds were the same as with the greater speed within the limits of errors of experiment.

BIAS.

Finally, to test the question if there were any bias in taking these observations, eight sets of observations were taken, in which the readings were made by another, the results being written down without divulging them. Five of these sets are given in the "specimen," pages 133-134.

It remains to notice the remarkable coincidence of the result of these experiments with that obtained by Cornu by the method of the "toothed wheel."

Cornu's result was 300400 kilometers, or as interpreted by Helmert 299990 kilometers. That of these experiments is 299940 kilometers.

POSTSCRIPT.

The comparison of the micrometer with two scales made by Mr. Rogers, of the Harvard Observatory, has been completed The scales were both on the same piece of silver, marked "Scales No. 25, on silver. Half inch at 58° F., too short .00009 inch. Centimeter at 67° F., too short .00008 cm."

It was found that the ratio .3937079 could be obtained almost exactly, if, instead of the centimeter being too short, it were too long by .00008 cm. at 67°.

On this supposition the following tables were obtained. They represent the value of one turn of the micrometer in millimeters.

Table 1 is the result from centimeter scale.

Table 2 is the result from half-inch scale.

Table 3 is the result from page 31.

It is seen from the correspondence in these results, that the previous work is correct.

PREFACE.

The preparation of the following catalogue was commenced at the Naval Observatory for the purpose of obtaining standard positions of reference stars for use in the lunar and planetary theories, especially in the reduction of the older occultations. It originally included only time stars, and stars occultations of which by the moon had been well observed.

In 1877 the unfinished work, along with other material pertaining to the lunar theory, was courteously turned over to the office of the American Ephemeris by Rear-Admiral Rodgers, United States Navy, the Superintendent of the Observatory. It was then found advisable to greatly enlarge the catalogue, so as to include all the standard stars of the American Ephemeris, and all the stars, down to the sixth magnitude, which could be occulted by the moon.

The work of reconstructing and completing the catalogue has been nearly all performed, under the personal direction of the writer, by Master Chauncer Thomas, United States Navy, to whose care and accuracy is due much of its value.

POSITIONS OF STANDARD CLOCK AND ZODIACAL STARS.

§ 1. INTRODUCTION.

In the reduction of all the Washington meridian observations since 1862, and in all the investigations of the motions of the planets by the author up to and including that of Uranus in 1873, the right ascensions depend fundamentally upon Dr. Gould's standard catalogue. The latter was published by the Coast Survey, and introduced into the American Ephemeris from the years 1865 to 1880.

When the work of reducing the older occultations of stars with modern data was undertaken at the Naval Observatory, it became necessary to have accurate positions of stars for dates much more remote than the time of Bradley, because a large number of the occultations selected were observed before 1700. As Dr. Gould's proper motions depended largely on Bessel's Bradley, which was to be superseded by Auwers's re-reduction of Bradley's observations, and as much other material had become available for the determination of accurate proper motions, it became necessary for the work in hand to redetermine the positions of the fundamental time-stars. So far as the right ascensions are concerned, this was done for the "Maskelyne stars" in 1872 The resulting "Right Ascensions of the Equatorial Fundamental Stars" appeared as an appendix to the Washington Observations for 1870.

One result of this investigation was the discovery of a periodic error in the right ascensions of a number of modern catalogues, which seems to have had its origin in some one of Pond's adopted catalogues, and to have disseminated itself among the results of many observatories through the employment of the earlier Greenwich star positions, which depend fundamentally upon those of Pond. When, after the practice of Professor Airy, new fundamental positions depending entirely on recent observations are formed from time to time, the error in question is gradually cut down, and, as a matter of fact, it has disappeared from the recent Greenwich results. But so long as the same fundamental catalogue is used, it will in consequence of erroneous proper motions, tend to increase with the time rather than diminish. By referring to the tables on page 46 of the paper cited, and the formulæ of correction which precede them, it will be seen that in the cases of the Greenwich, Oxford, Paris, and Washington results, the right ascensions about 9^h are very generally too great relative to those about 21^h, the difference ranging from 0.º10 in the case of Oxford (Radcliffe, 1845) to 0.º03 in the case of the Greenwich 7-year catalogue for 1864.

The necessity of reobserving a large number of the occulted stars, as well as the pressure of other duties, caused the work to be laid aside until 1876, when the means for recommencing it became available. It was the original intention to reduce the

declinations to Auwers's standard, copious tables for doing which are given in the Astronomische Nachrichten. But it was found that in the mean time a very exhaustive discussion of the declinations of the principal fixed stars, and of the systematic corrections necessary to reduce the declinations of the different catalogues to a fundamental system, had been undertaken by Mr. Lewis Boss, then of the Northern Boundary Survey, but now Director of the Dudley Observatory, Albany. An examination of Mr. Boss's work led me to believe that in the thoroughness with which the bases of all existing original catalogues of value were examined and discussed, and in the correctness of the general principles on which the work was being executed, it left little to be desired. The only serious deficiency seemed to be the absence of Auwers's reduction of Bradley's declinations from the data employed, an absence which I regretted, but which could not be satisfactorily supplied. Altogether, I judged it best to adopt Mr. Boss's declinations as the standard of reduction, and have to express my indebtedness to Maj. W. J. Twining, Corps of Engineers, U. S. A., chief astronomer of the American branch of the survey, as well as to Mr. Boss, for the communication of all the tables and data necessary to reduce the declinations of different catalogues to Mr. Boss's system.

The zodiacal stars in the original catalogue, above described, included only those of which occultations had been actually observed up to 1870. On taking charge of the America Ephemeris the need of a complete revision of the stars which might be occulted by the moon was found to be pressing. It was therefore decided to extend the catalogue so as to include all stars to the sixth magnitude, inclusive, which could be occulted by the moon. Stars below this magnitude were included only when found in Bradley's catalogue or when occultations had actually been observed

In preparing the original list, which was that employed in investigating the motion of the moon before 1750, the provisional declinations of Dr. Auwers, reduced to Boss's system, were used for the epoch 1755. In the mean time Dr. Auwers had worked out his definitive results for Bradley's declinations, and it was deemed best to incorporate them in the whole catalogue. The original places were therefore modified so as to give the results which would have been reached had Auwers's declinations been used in the first place.

The catalogue here presented may therefore be considered as including two classes of stars:

- (1) All the standard stars of the American Ephemeris, omitting for the most part those added for field work.
- (2) All stars to the sixth magnitude, inclusive, which can be occulted by the moon, together with stars below the sixth magnitude which had been observed by BRADLEY.

§ 2. FORMATION OF RIGHT ASCENSIONS.

Owing to the constant improvements still in progress in the art of determining star positions, the time has not yet arrived when a fundamental catalogue can be regarded as entirely definitive. It is not, therefore, deemed necessary to present in detail the deduction of the position of each separate star, but it is considered sufficient to give a general statement of the method pursued.

The method of forming the definitive right ascensions of the original catalogue was to compare the catalogue places with computed provisional places, and, assuming the corrections thus obtained to be of the form a+b T, to find the values of a and b by least squares. These quantities were the corrections to be applied to the provisional right ascensions and proper motions.

As a general check upon the accuracy of all the work, two fundamental epochs were adopted, namely, 1755.0, the epoch of Bessel's and of Auwers's reductions of Bradley, and 1850.0, that most generally adopted as the zero epoch for the theoretical astronomy of the present time. Approximate positions for these two epochs (supposed to be correct to 0°.3 of time in R. A, and to 0'.1 in declination) were obtained for these epochs, generally from Bessel's Fundamenta and the British Association Catalogue. The precessions and secular variations of the annual motion for each epoch were then independently computed. In these computations Struve's constant of precession and Hill's formulæ, as found in the Star Tables of the American Ephemeris and in my paper of 1872, already cited, were made use of. It will be remarked that the secular variations thus computed are not those of the precession simply, but of the annual variation. The difference, however, is not great, except in cases of stars having considerable proper motion or high declination. The annual precessions were computed to 0°0001, and the variations in 100 years to the same order of units

The provisional right ascensions of the stars were then carried forward from Auwers's Bradley, neglecting proper motion entirely, and assuming the precession to vary uniformly between 1755 and 1850. The computed values of the secular variation were therefore substantially unused in obtaining the provisional places, except as a check against serious error. Practically the adopted value of this variation was of the difference between the precession for 1755 and that for 1850. The residual corrections given by the several catalogues thus represented proper motions from 1755. To guard against an accumulation of small errors, the computations of the provisional places were carried to .º001.

In the case of stars of the American Ephemeris, a course different in some respects was pursued.

The annual variations and secular variations for 1860 being given in the Star Tables of the American Ephemeris, it was not considered necessary to compute them for 1850. The secular variations were, however, computed for 1755 to five places of decimals, the difference between this and the corresponding quantity for 1860 giving the term depending on the third power of the time. The right ascensions were then carried back to the epochs of the catalogues, supposing the annual variation and secular variation of the Star Tables to be exact for 1860, and including the term depending on the third power of the time. The provisional proper motions were therefore included.

The computed places thus obtained for each class of stars were then compared with those given in the following catalogues.

1. Bradley, 1755.—The right ascensions were those of Dr. Auwers's, as communicated in manuscript. In the case of a few stars, however, Bessel's places, as given in the Fundamenta Astronomiæ, had to be used.

- 2. Piazzi, 1800.—Precipuarum Stellarum Inerrantium Positiones Mediæ. Panormi, This catalogue was used in the case of stars not observed by Bradley.
 - 3. Struve, 1830.—Catalogue in the Positiones Media.
- 4. Argelander, 1830.—DLX Stellarum Fixarum Positiones Media, ineunte anno 1830. Helsingfors, 1835.
 - 5. Pond, 1830.—Catalogue of 1112 stars. London, 1833.
- 6. Airy, 1830.—First Cambridge catalogue of 726 stars in the Memoirs of the Royal Astronomical Society, vol. xi.
- 7. Johnson, 1830.—St. Helena catalogue of 606 stars. London, 1835. (Used only for two or three southern stars.)
- 8. Gilliss, 1840.—Catalogue in Observations made at the [old] Naval Observatory. Washington, 1846.
 - 9. Armagh, 1840.—Robinson's catalogue.
 - 10. Airy, 1840. The Greenwich twelve-year catalogue.
- 12. Pulkowa, 1845.—Catalogue in vol. I of the Pulkowa observations, derived from observations with the transit instrument.
 - 13. Airy, 1850.—Greenwich six-year catalogue for 1850.
- 14. Pulkowa, 1855.—Catalogue from observations with the meridian circle, communicated in manuscript by Director Struve.
 - 15. Airy, 1860.—Greenwich seven-year catalogue.
- 16. Yarnall, 1860.—Washington catalogue. Appendix to Washington observations for 1871.
 - 17. Airy, 1864.—Second Greenwich seven-year catalogue.
- 18. Engelmann, 1866.—Resultate aus Beobachtungen am Meridiankreise der Sternwarte zu Leipzig, von Dr. Rudolph Engelmann.
- 19. Greenwich, 1870.—Mean result from the Greenwich observations from 1868 to 1876, inclusive.
- 20. Washington, 1870.—Mean results from all observations with the Washington Transit circle from 1866 to 1873.

To the positions of the separate catalogues were applied the systematic corrections given on pages 43 to 47 of the paper on the right ascensions of the equatorial fundamental stars.

The weights assigned to the several catalogues, as dependent on the number of observations, were founded upon a consideration of the probable systematic and accidental errors of each catalogue. While such considerations do not constitute a refined discussion, I consider that the final results will be much nearer to those which would be given by the most refined discussion than to those given by the usual mode of combining catalogue results. I also consider that the former difference will be much less than the probable error of the best results. The following is the table made use of, the argument at the top being the number of observations.

Tables of adopted weights in right ascension.

Assuming the residuals to be represented by an expression of the form a+bT, T being the fraction of a century after 1850.0, the equations of condition thus obtained were solved by least squares. The definitive correction to the provisional right ascension for 1850 was then a, and to that for 1755 was a-0.95b. These corrections being applied to the provisional places, corrected places for the two fundamental epochs would then be obtained.

The process thus described was not rigorous with respect to the third place of decimals in the seconds owing to three causes.

- (1) The limitation of the adopted annual precession to the fourth decimal.
- (2) The neglect of the secular variation of the proper motion, which would introduce a small term varying with the time.
- (3) The assumption that the secular variation of the centennial motion was constant.

The errors thus introduced were entirely unimportant so far as the immediate purpose was concerned, because they were smaller than the necessary uncertainty of the results; but it was considered desirable that the relation between the final positions in the catalogue, and the precessions and proper motions, should correspond accurately to a uniform theory. The results were therefore checked and adjusted by the following process.

The centennial variation for 1850 was obtained in the first place by correcting that value of the precession or centennial variation for 1850, which was used in computing the provisional places, by the quantity b, derived from the equations of condition. The

value thus employed for correction was not generally the same as the definitive precession for 1850, because the latter was afterward computed to one more place of decimals. But the corrected result was considered as the definitive variation for the epoch 1850.

The centennial variation for 1755 was derived from that for 1850 by subtracting from the latter the quantity

 $\frac{1}{2}(s_1+s_2) \times (1-\frac{1}{20})$

 s_1 and s_2 being the secular variations for the respective fundamental epochs.

Having thus obtained the centennial variations, which we may call v_1 and v_2 , for the two fundamental epochs, the change of right ascension between those two epochs was independently computed by the formula

$$\triangle \text{ R.A.} = \frac{1}{2} (v_1 + v_2) (1 - \frac{1}{90}) - 0.075 (s_2 - s_1)$$

Had the data and method of interpolation of the provisional places of the stars been perfectly consistent with the definitive quantities, the right ascension for 1755, obtained by subtracting \triangle R.A. from the right ascension for 1850, would have agreed exactly with that obtained by correcting the provisional place. But, owing to the want of a rigorous reduction already pointed out, small discordancies were to be expected. In a large majority of cases the discordance was less than o.o. and rarely or never amounted to o.o. unless from some error of computation to be rectified. It was then judged best to render the right ascensions for 1755 and the centennial variations consistent with each other by an adjustment. In general one-third the discordance was applied to the place for 1755 and two-thirds to the centennial variation. But this proportion was subject to change in exceptional cases. The general result aimed at was that the numbers should be as nearly as possible the same as if a rigorous theory had been adopted at the outset.

The above descriptions apply only to the original catalogue. In the extension of it made by Master Chauncey Thomas, U. S. N., it was considered better to use the more elegant process of reducing each catalogue place to 1850 by precession alone and then to obtain the position and proper motion for this epoch by the usual method.

In the original formation of a catalogue, assuming the proper motions to be entirely unknown, this is the preferable process. But in future it will probably be found more convenient, at least in the case of fundamental stars, to reduce the provisional places to the epoch of each catalogue and work only with the residual differences between the two positions. This is in fact using the general astronomical method of correcting elements.

Ulterior details respecting the construction of the catalogue, will be given in connection with it.

§ 3. FORMATION OF THE DECLINATIONS.

As already stated, the normal catalogue to which all the declinations are reduced is that of Mr. Lewis Boss. This catalogue has since been published as Appendix H to the American Report of the Northern Boundary Commission.*

^{*}Reports upon the Survey of the Boundary between the Territory of the United States and the Possessions of Great Britain from the Lake of the Woods to the Summit of the Rocky Mountains, authorized by an act of Congress approved March 19, 1872. Archibald Campbell, esq., Commissioner; Capt. W. J. Twining, Corps of Engineers, breves major U. S. A., Chief Astronomer. Washington: Government Printing Office. 1878.

The most important modification which had to be made in using Mr. Boss's tables arose from the substitution of Auwers's reduction of Bradley's observations for that of Bessel. Mr Boss's systematic corrections were applicable only to Bessel's positions. It was therefore necessary to find the correction to be applied to Auwers's declinations in order to reduce them to the same fundamental system. Boss's systematic correction to each of Bradley's zodiacal stars was taken from the table, which has since been published, page 496 [90] of Mr. Boss's paper, and the result compared with Dr. Auwers's definitive reduction.

It would have been much better had all the zodiacal stars of Mr. Boss's catalogue been definitely reduced to 1755 and compared with Auwers's corrections. This course was not, however, at the time practicable.

The following table shows the mean result for each hour of right ascension in the sense of Boss's correction to Auwers's definitive declination. The argument 0° gives the mean result for all the stars between 23^h 30^m and 0^h 30^m of right ascension; the argument 15° the mean result from 0^h 30^m to 1^h 30^m, etc.:

Right ascension.	Boss-Auwers.	Number of stars.	Right ascension.	Boss-Auwers.	Number of stars
v,			0	"	
0	+0.98	30	180	+2.58	17
15	1. 70	37	195	2. 48	25
30	1.65	28	210	2.99	19
45	1.61	35	225	2. 29	26
60	1.45	67	240	2. IO	31
75	o. 89	34	255	1.64	26
90	1. 57	45	270	I. 47	26
105	0. 74	39	285	1.06	30
120	1. 14	44	300	1.60	25
135	1. 71	37	315	o. 65	36
150	2. 14	33	330	0. 71	47
165	+2.66	31	345	+0.66	37

It will be remarked that since the stars to which this table refers are on the average within 3° or 4° of the ecliptic the corrections are functions both of the right ascension and declination. Owing, however, to this arrangement, it is impossible to separate quantities depending on the right ascension from those depending on the declination. The best practical course, therefore, seems to be to leave in abeyance the general form of correction and to tabulate it as a function of the right ascension alone. Developing the residuals in the usual way the result is—

Boss—Auwers =
$$+ 1''.60 - 0''.68 \cos \alpha + 0''.32 \cos 2 \alpha - 0.10 \sin \alpha + 0.38 \sin 2 \alpha$$

In cases of this sort the terms in 2 α are generally to be regarded as accidental. It was therefore deemed best to omit them and to apply only the expression

$$+ 1''.60 - 0''.68 \cos \alpha - 0''.10 \sin \alpha$$

In applying this correction to Auwers's results from Bradley's observations I do not wish to be considered as indorsing its reality, but have used it only in order that all the declinations might be reduced to the same system. I believe that considerable

weight would have been added to Boss's results had he been able to use Auwers's Bradley as one of the normal catalogues. It may be expected that the additional data accumulated during the next fifteen or twenty years will lead to a more certain result.

Catalogues used for Declinations.—These were, in the main, the same as in the case of the right ascensions, with the following additions:

- (1) Cambridge, 1840.—Mean results from the Cambridge observatories from 1836 to 1844, as found in the several annual volumes of observations.
- (2) Paris, 1860.—Mean results from the Paris observations of 306 "étoiles fondamentales" made with the Gambey mural circle, 1854-'63, as found in the several annual volumes of observations.
- (3) Paris, 1865.—Similar results from the observations with the new meridian instrument, 1863-'67.
- (4) Melbourne, 1870.—First Melbourne General Catalogue of 1227 stars for the epoch 1870. Melbourne, 1874.

The several tables of systematic corrections which have been applied, and the weights, as dependent on the number of observations, will be found in Mr. Boss's work, pages 560-567.

The deduction of the definitive declinations has been carried out in the same way as in the case of the right ascensions. The most important modifications were these:

- (1) An approximate proper motion was used in interpolating the provisional places compared with the several catalogues.
- (2) In the same interpolation account was taken of the change in the secular variation of the annual motion; in other words, the term multiplied by the cube of the time was retained.
- (3) All the results were computed to o".o1, with the definitive values of the annual motions.

In consequence of these changes, the average discrepancy between the places for 1755, as obtained by applying the computed correction, a = 0.95 b, to the provisional place, and those obtained by direct computation from the definitive centennial motions is less than 0''.02.

§ 4. POSITIONS OF THE NINE PRINCIPAL STARS OF THE PLEIADES.

The mode of treating the stars of this group was in some points exceptional. A question which naturally presents itself in investigating their positions is that of their relative proper motion. We might proceed on either of two hypotheses; first, that the place of each star is to be determined independently on the supposition that its proper motion is independent of that of the others; second, that they all have a common and equal proper motion. If the differences of the proper motions decidedly exceed the probable errors of the separate determinations, we should choose the first hypothesis; otherwise the second. On either hypothesis our first step must be to determine each star independently, and this was done in the same way as with all the other stars. It was thus found that there was no conclusive evidence of change from the meridian observations alone, and that the common proper motions + 0°.088 in R. A. and - 5".87 in declination for the entire group, would satisfy all these observations within their possible limits of error.

As a still further test of the invariableness of their relative positions, and a means of further correcting these positions, the triangulations of Bessel and of Wolf were called into requisition. The former work is found in Bessel's Astronomische Untersuchungen, vol. 1, pp. 209-238, the latter in the Comptes Rendus of the French Academy for 1875. It has since appeared in Annales de l'Observatoire de Paris, Memoires, XIV.

The date of Bessel's triangulation is 1840, that of Wolf's 1874, so that the elapsed time exceeds one-third of a century. Both of these sets of positions were reduced to 1850 with the common proper motion already given, and the results compared with the meridian observations. There was no marked resemblance between the signs of the differences Wolf—Bessel and the signs of the relative proper motions indicated by the meridian observations; so that an additional proof of the unreality of these proper motions was obtained. I therefore conclude that although a certain amount of relative proper motion must exist in this group, yet the apparent motions, as observed, are as much due to errors of observation as to the actually existing motions, and when the latter shall finally be discovered they will, on the average, be found as near to zero as to the values indicated by all the observations yet made. Consequently, the most probable values of these relative proper motions must be regarded as zero.

It is evident that from the data described we shall have two classes of results for the position of each individual star of the group. The one is the result of the meridian observations of that particular star; the other the result of the triangulations between that and all the other stars, combined with the meridian observations of those other stars.

Since the triangulation can give only relative positions, the mean of the entire group should remain as determined by the meridian observations. We must therefore apply to the results of the triangulations such constant corrections that this result shall be attained. These corrections are:

In combining the several results, the relative weights assigned were as follows:

In R. A. In Dec.

Mer. obs., Wt.
$$\equiv$$
 1

Bessel, "Wt. \equiv 2

Wolf, "Wt. \equiv 1

Wolf, "Wt. \equiv 2

Wolf, "Wt. \equiv 2

The several steps of the process thus described are shown in the following table. The small figures after the individual proper motions show the relative weights which have been assigned to them. The mean common proper motion of the group obtained by their combination is—

In R. A.,
$$\mu = +$$
 o*.088
In Dec., $\mu = -5''.87$

§ 5. DECLINATIONS OF SIRIUS AND PROCYON.

SIRIUS.

In his researches on the variable proper motion of Sirius (Publication VII der Astronomischen Gesellschaft, Leipzig, 1868), Auwers has found a correction, r, to its declination, defined as follows: Let r_1 and r_2 be the respective corrections to be applied to the declinations of Sirius in the Tabulæ Regiomontanæ, in order that this declination may be correct relatively to those of β Orionis and α Hydræ, respectively. Then Auwers puts

$$r=\frac{1}{2}\left(r_1+r_2\right)$$

It follows that if the corrections to the declinations of β Orionis and α Hydræ in the *Tabulæ Regiomontanæ* are respectively Δ_1 and Δ_2 , the correction to the declination of Sirius in the same tables will be

$$\frac{1}{2}(\Delta_1+\Delta_2)+r$$

By comparing the positions of β Orionis and α Hydræ in Boss's catalogue with those of the *Tabulæ Regiomontanæ*, we find:

$$\Delta_{1} = + 1.48 + 2.44 T + 0.01 \times \frac{1}{2} T^{2} - 0.22 \times \frac{1}{6} T^{3}$$

$$\Delta_{2} = + 1.29 + 0.89 + 0.35 + 0.76$$

$$\frac{1}{2} (\Delta_{1} + \Delta_{2}) = + 1.38 + 1.66 + 0.18 + 0.27$$

T being counted from 1850. AUWERS finds for the value of r:

$$r = + 0^{\prime\prime}.84 + 1^{\prime\prime}.47 T + P^{\prime}$$

P' representing the purely periodic term arising from the orbital revolution of the companion of Sirius. The total correction to the place of Sirius in the Tabulæ Regiomontanæ would then be

$$+2''.23 + 3''.13 T + 0''.18 \times \frac{1}{2} T^2 + 0''.27 \times \frac{1}{6} T^3 + P'$$

But by comparing the secular variation of the centennial motion, — 37" 44 + 0".13 T, with that of Bessel, — 38."0, it seems that the actual correction must be of the form—

$$a + bT + o''.56 \times \frac{1}{2}T^2 + o''.13 \times \frac{1}{6}T^3 + P'$$

The difference in the coefficients of T² will produce a difference of only o".17 in the declinations for 1755; we may therefore omit any adjustment on account of it, and put for the total correction to the declination of Sirius—

$$+2''.23 + 3''.13 T + 0.56 \times \frac{1}{2} T^2 + 0''.13 \times \frac{1}{6} T^3 + P'$$

PROCYON.

The declination of this star is determined on the same principle with that of Sirius, from the investigation of Auwers in his paper.

The comparison is, however, made, not with the *Tabul Regiomontana*, but with the *Tabulæ Reductionum* of Wolfers. The stars of comparison are α Ceti, α Orionis, α Serpentis, γ , α , and β Aquilæ, and α Aquarii, but the three stars of Aquila receive only the weight of two. In the value of Δ we may omit writing the terms depending on T^2 and T^3 , since they are not used in obtaining the final result. By comparing

the corrections of Wolfers to the Tabulæ Regiomontanæ with the declinations of the present paper we find the following values of \triangle :

```
α Ceti
                              \Delta^1 = + 0.04 + 1.88 \,\mathrm{T}
                              \Delta_2 = + 0.18 + 0.76
α Orionis -
α Serpentis
                              \Delta_3 = -0.50 - 2.66
y Aquilæ -
                              \triangle_4 = -0.35 - 1.45
α Aquilæ -
                              \Delta_5 = -0.40 - 1.35
β Aquilæ -
                              \triangle_6 = -0.12 - 102
α Aquarii -
                              \Delta_7 = -0.24 - 1.06
Mean by weights
                              \triangle = -0.18 - 0.605 \text{ T}
                                    +0.39 + 0.931 T + P'
Auwers's r
                                    +0.204+0.326 T+P'
Total correction
```

This correction, omitting P', being applied to the place of the Tabulæ Reductionum, gives the declination in the table.

§ 6. CIRCUMPOLAR STARS.

In the case of stars within 30° of the pole an accurate reduction between epochs a century apart cannot be effected without other data than those given for the ecliptic and time stars. It was judged that the convenience of astronomers using the catalogue would be subserved by presenting data for the stars in the same general form as for others, with the addition of such intermediate epochs that the reductions could be effected without the employment of higher powers of the time. Hence stars between 10° and 30° from the pole have data given for each half century, or to speak more exactly, for the epochs 1755, 1800, 1850, and 1900. In the case of stars yet nearer the pole the epochs 1755, 1825, and 1875 are added.

The declinations of the circumpolar stars are all taken from Boss's catalogue for the epoch 1875.

The right ascensions have not been independently investigated, but are taken from the second edition of Dr. Gould's catalogue, published by the United States Coast Survey, and based upon Dr. Gould's extended investigations found in Volume VI of the Astronomical Journal. Although these right ascensions may be at the present time susceptible of correction, it was judged best to adhere to them for the following reasons:

- 1st. They had been retained in the American Ephemeris for 1881, in which new declinations had been introduced, and it was judged best to make changes only at few epochs. They had also been so extensively used by the Coast Survey and other authorities as to form a standard of reference which it was desirable not to change except when a great and permanent improvement was possible.
- 2d. Their definitive amelioration is not practicable until Dr. Auwers's reductions of Bessel's observations are available.
- 3d. Each astronomer can readily apply for himself such corrections as may appear necessary.

It will probably be found that the easiest way of making these corrections will

be to reduce each star to the epoch of the catalogue of observation and work with the correction thus indicated for that particular epoch. For all except two or three of the closest polar stars the correction of each co-ordinate may be assumed to increase uniformly with the time.

To form a set of data in which the positions, centennial variations, and secular variations for each epoch should be perfectly consistent throughout, several trouble-some modifications were found necessary. The coefficients of reduction given by Gould and Boss, respectively, could not be used unchanged, because those for each co-ordinate depended upon the value of the other co-ordinate, and must therefore be changed with it. It was therefore necessary to compute anew for each epoch the constants corresponding to it and to combine these results in such a way as to secure homogeneity and consistency.

In the case of the close polar stars both the positions and the proper motions were reduced from 1855 to the several epochs by the rigorous trigonometrical formulæ, the constants being those founded on Struve's precession. These reductions were, in the first place, made with Dr. Gould's proper motion in declination, but it was easy to correct them, so that they should give Boss's proper motion for the epoch 1875.

The positions and proper motions for this epoch include all the data necessary for computing the precessions and secular variations for the different epochs. The centennial variations were then found by applying the proper motion to the precession. The original reductions were next checked by computing the change of position between each pair of consecutive epochs from the centennial variations, secular variations, etc., and comparing it with the actual difference given by the trigonometrical reduction.

In the case of stars more than 15° from the pole the trigonometrical reduction was not necessary. Generally Dr. Gould's coefficients gave results which need little correction, and this little, when necessary, was derived from the computed elements of motion for the different epochs.

§ 7. EXPLANATION OF THE CATALOGUE.

The catalogue is arranged so that all the data pertaining to the right ascension shall be on the left-hand pages, and those pertaining to the declinations on the right-hand pages.

In the case of the stars observed by Bradley, the positions and other data are given for the two fundamental Besselian epochs 1755.0 and 1850.0. In some cases stars not observed by Bradley have been given for both of these epochs. In the case of fundamental time stars the positions are also given for 1900. The precession and secular variation for each epoch are independently computed, so that their general agreement will serve as a check upon their accuracy.

On the left-hand page the fourth column gives, opposite the epoch 1755, the number of observations made by Bradley in right ascension. Opposite 1850 is given the number of observations made at Greenwich, Pulkowa, and Washington since 1840, which have been used in preparing the catalogue.

Observations at other observatories have been omitted in the enumeration.

although employed in obtaining the final result. In some cases, as, for instance, those of the Pulkowa fundamental time stars, no precise number of observations could be assigned. The object of this column is rather to give a general idea of the weight of the result than a precise enumeration of the observations.

Column Right Ascension gives the right ascension of each star for the several epochs, as already explained. The epoch 1850 has been taken as a fundamental one, and, for the most part, the positions for other epochs have been derived from those for 1850 by the centennial variation, etc., deduced from observations.

The equinox to which all the stars are reduced is that of my paper of 1872 on the Right Ascensions of the Equatorial Fundamental Stars. (Washington Observations for 1870, Appendix II.) The results obtained by Dr. Auwers for Bradley's equinox, and the recent Greenwich observations, render it probable that the adopted equinox is nearly correct for 1850, but that the centennial variations require a general correction of perhaps — 0°.05. Further researches are, however, necessary before a definitive result for the motion of the equinox can be derived.

The right ascensions of the 32 Maskelyne stars in the investigation of 1872 are transferred without alterations to the present catalogue

The centennial variation derived in the first place for the epoch 1850 has usually been regarded as a fundamental one, and that for other epochs has been derived from it by the secular variations given in the following column.

The precessions are computed strictly from STRUVE's constant, using the formulæ given in the star tables of the American Ephemeris and in part reprinted on p. 172 of the present paper. But, as a general rule, the precessions and secular variations were derived before the definitive positions of the stars were worked out, and did not, therefore, in all cases accurately correspond to the finally concluded positions. In general, however, where any important discrepancy would thus be produced, the precessions and secular variations have been recomputed with the definitive data.

The proper motions are generally obtained by subtracting the precessions from the centennial variations. The differences among the proper motions thus found arise partly from incongruity of the data, imperfections of calculation, etc., but mostly from the change in the direction of the meridian produced by precession.

With a view of detecting any serious error in the proper motions the secular variation of the proper motion has been independently computed by the formula given in the present paper in the case of those stars of the American Ephemeris which have a considerable proper motion. The result of this computation is given in the last column.

In the case of circumpolar stars the above method of obtaining the centennial variations for the different epochs would not always have been reliable. In this case, therefore, the secular variation of the proper motion was carefully computed for several epochs and the proper motions for past and future epochs obtained by applying the changes thus indicated to the proper motions for the fundamental epoch. The precessions being also computed for the different epochs, the centennial variations were obtained by applying the proper motions to them.

On the right-hand pages the third column gives, for the epoch 1850, the magnitudes of the stars taken in the order of preference from the following authorities.

- 1. Gould, Uranometria Argentina.
- 2. Heis, Atlas Coelestis Novus, Köln, 1872.
- 3. Argelander, Bonner Sternverzeichniss, commonly called the Durchmusterung; Astronomische Beobachtungen auf der Sternwarte zu Bonn, vols. iii, iv

Opposite epoch 1755 are given the magnitudes of Bessel's Fundamenta.

In both cases the fractions of a magnitude are expressed decimally.

The general method of arranging the data for the declinations is substantially the same as for the right ascensions, and therefore needs no additional explanation.

§ 8. FORMULÆ FOR REDUCING THE CATALOGUE PLACES TO OTHER EPOCHS.

It is supposed that the data given in connection with the place of each star will suffice for its reduction to any epoch between 1750 and 1900, by TAYLOR'S Theorem. To effect this we take the catalogue epoch nearest that to which the star is to be reduced, and put—

- T, the interval, in units of a century.
- α_0 , the star position for the catalogue epoch.
- c_{o} the centennial variation for the same epoch.
- s, the secular variation for the same epoch.
- s', the derivative of s at this epoch, the unit of time being a century.
- s", the second derivative of s, etc.

Then:

$$\alpha = \alpha_0 + T c_0 + \frac{1}{2} T^2 s_0 + \frac{1}{6} T^3 s_0' + \frac{1}{24} T^4 s_0'' + \text{etc.}$$
 (1)

The values of c_0 and s_0 are always given in the catalogue. Those of s'_0 , s''_0 , etc., will not always be required, but when required, are readily deduced from the values of s for different catalogue epochs.

In the most general case the values of s'_0 , s''_0 , etc., may be formed from the successive differences of s by the usual formulæ, namely, these differences being arranged according to the following usual scheme:

where

$$\Delta'_{-1} = s_{-1} - s_{-2}
\Delta'_{-1} = s_{0} - s_{-1}
\Delta'_{1} = s_{1} - s_{0}
\text{etc.,}$$

$$\Delta''_{-1} = \Delta'_{-1} - \Delta'_{-1}
\Delta''_{0} = \Delta'_{1} - \Delta'_{-1}
\Delta''_{1} = \Delta'_{1} - \Delta'_{1}
\text{etc.,}$$
etc., etc.

we put

$$\Delta_{0}' = \frac{1}{2} (\Delta_{-i}' + \Delta_{i}')$$

$$\Delta_{0}''' = \frac{1}{2} (\Delta_{-i}''' + \Delta_{i}''')$$
etc., etc.

and then find

$$s_{0}' = \frac{ds}{dT} = n \ (\triangle_{0}' - \frac{1}{6} \triangle_{0}''' + \frac{1}{30} \triangle_{0}^{v} - \text{etc.})$$

$$s_{0}'' = \frac{d^{2}s}{dT^{2}} = n^{2} \ (\triangle_{0}'' - \frac{1}{12} \triangle_{0}^{iv} + \text{etc.})$$

$$s_{0}''' = \frac{d^{3}s}{dT^{3}} = n^{3} (\triangle_{0}''' - \frac{1}{4} \triangle_{0}^{v})$$

n being the factor by which the interval between epochs must be multiplied to make 100 years. These values of s are to be introduced into the equation (1).

When several reductions are to be computed to the same epoch it may be a little more convenient to introduce \triangle' , \triangle'' , etc., directly into the formulæ instead of s', s'', etc. If we make this substitution, stopping at s''' and \triangle''' , the result will be

$$\alpha = \alpha_0 + Tc_0 + \frac{1}{2}T^2s_0 + \frac{n}{6}T^3\Delta'_0 + \frac{n^2}{24}T^4\Delta''_0 + \left(\frac{n^3}{120}T^5 - \frac{n}{36}T^3\right)\Delta'''_0$$

It will be remarked that the coefficients of \triangle_0' , \triangle_0'' and \triangle_0''' will be very minute fractions, so that these quantities are not required with great precision. When, owing to the epoch being near the end of the series, their values are not given by differencing, they may be found with sufficient accuracy by extending the successive orders of differences by induction.

When the interval is 95 years, $n = \frac{20}{19}$ When the interval is 50 years, n = 2When the interval is 45 years, $n = \frac{20}{9}$ When the interval is 25 years, n = 4When the interval is 20 years, n = 5

REDUCTION BETWEEN TWO CATALOGUE EPOCHS.

As a check upon the numbers of the catalogue it is desirable to compute the change of position between two catalogue epochs in order to see whether it agrees with the difference between the assigned positions. The following is a simple way of effecting this. Put

 c_0 , s_0 , etc., the centennial variation, etc., for the first epoch; c_1 , s_1 , etc., the same for the second epoch; t the fraction of a century between the epochs; α_t the position for the middle of the elapsed interval. Then—

$$\alpha_{i} = \alpha_{0} + \frac{t}{2} c_{0} + \frac{t^{2}}{8} s_{0} + \frac{t^{3}}{48} s'_{0} + \frac{t^{4}}{384} s'' + \frac{t^{5}}{3840} s'''$$

$$\alpha_{i} = \alpha_{1} - \frac{t}{2} c_{1} + \frac{t}{8} s_{1} - \frac{t^{3}}{48} s_{1} + \frac{t^{4}}{384} s''_{1} - \frac{t^{5}}{3840} s'''_{1}$$

whence

$$\alpha_{1} - \alpha_{0} = \frac{t}{2} (c_{1} + c_{0}) - \frac{t^{2}}{8} (s_{1} - s_{0}) + \frac{t^{3}}{48} (s'_{1} + s'_{0}) - \frac{t^{4}}{384} (s''_{1} - s''_{0}) + \frac{t^{5}}{3840} (s''_{1} + s'''_{0}) - \text{etc.}$$

Since each of the quantities c, s, s', etc., is the derivative of the preceding one, their differences are given by a series of the same kind, namely:

$$s_{1} - s_{0} = \frac{t}{2} (s'_{1} + s'_{0}) - \frac{t^{2}}{8} (s''_{1} - s''_{0}) + \frac{t^{3}}{48} (s'''_{1} + s'''_{0}) - \text{etc.}$$

$$s''_{1} - s''_{0} = \frac{t}{2} (s'''_{1} + s'''_{0}) - \text{etc.}$$

Making these substitutions we find:

$$\alpha_1 - \alpha_0 = \frac{t}{2} (c_1 + c_0) - \frac{t^3}{24} (s_1' + s_0') + \frac{t^5}{240} (s_1''' + s_0''')$$

From the equations which give the values of the derivatives of s in terms of its differences, putting $n = \frac{1}{t}$, we have by simple reductions:

$$s'_0 + s'_1 = \frac{1}{t} \left(2 \triangle'_{i} + \frac{1}{6} \triangle'''_{i} \right)$$

 $s'''_1 + s'''_0 = \frac{2}{t^3} \triangle'''_{i}$

Making these substitutions in the value of $\alpha_1 - \alpha_0$, it reduces to

$$\alpha_1 - \alpha_0 = \frac{t}{2} (c_1 + c_0) - \frac{t^2}{12} \Delta_1' + \frac{t^2}{720} \Delta_1'''$$

The following are special cases of this formula:

A. Interval, 95 years:

$$\alpha_1 - \alpha_0 = 0.475 (c_1 + c_0) - 0.075 \Delta_1^2$$

which may be readily computed when put into the form-

$$\alpha_1 - \alpha_0 = \frac{c_1 + c_0}{2} \left(1 - \frac{1}{20} \right) - \frac{3}{40} \Delta_1'$$

B. Interval, 50 years:

$$\alpha_1 - \alpha_0 = \frac{c_1 + c_0}{4} - \frac{1}{48} \Delta_{\frac{1}{2}}' + \frac{1}{2880} \Delta_{\frac{1}{2}}'''$$

C. Interval, 25 years:

$$\alpha_1 - \alpha_0 = \frac{c_1 + c_0}{8} - \frac{1}{102} \Delta_1' + \frac{1}{11520} \Delta_1'''$$

REDUCTION TO ANY EPOCH.

The following are the principal special forms which will be found useful in reduction to different epochs. They vary with the number and interval of the catalogue epochs, and are therefore classified accordingly.

CLASS A.—Zodiacal stars.

Epochs 1755, 1850.

For 1850 + T

$$\alpha \equiv \alpha_0 + T c_0 + \frac{1}{2} T^2 s_0 + \frac{1}{6} \frac{20}{10} T^3 \triangle s_1$$

 $\triangle s$ being the increment of the secular variation from 1755 to 1850. Especially, to reduce to—

1860,
$$\alpha = \alpha_0 + \frac{1}{10}c_0 + \frac{1}{200}s_0$$

1870, $\alpha = \alpha_0 + \frac{1}{5}c_0 + \frac{1}{50}s_0 + \frac{1}{712}\triangle s$
1875, $\alpha = \alpha_0 + \frac{1}{4}c_0 + \frac{1}{32}s_0 + \frac{1}{365}\triangle s$
1880, $\alpha = \alpha_0 + 0.3c_0 + 0.045s_0 + 0.0047\triangle s$
1890, $\alpha = \alpha_0 + 0.4c_0 + 0.080s_0 + 0.0112\triangle s$
1900, $\alpha = \alpha_0 + \frac{1}{2}c_0 + \frac{1}{6}s_0 + 0.0219\triangle s$

For corresponding epochs before 1850, as far back as 1800, change the signs of the coefficients of c_0 and of $\triangle s$.

For epochs between 1755 and 1800 take the values of c and s corresponding to 1755 and count T from this epoch.

CLASS B.—Time and standard stars.

Epochs 1755, 1850, 1900.

For epochs previous to 1850, compute as in Class A. For epochs between 1850 and 1900 put

 c_0 , centennial variation for 1850.

 c_1 , centennial variation for 1900.

 s_0 , secular variation for 1850.

 s_1 , secular variation for 1900.

 Δ 's, secular variation for 1900 minus secular variation for 1850

Then in general, we may use either of the forms-

$$\alpha = \alpha_0 + T c_0 + \frac{1}{2} T^2 s_0 + \frac{1}{3} T^3 \triangle s \quad . \quad . \quad (T \text{ from 1850})$$

$$\alpha = \alpha_1 + T c_1 + \frac{1}{2} T^2 s_1 + \frac{1}{3} T^3 \triangle s \quad . \quad . \quad (T \text{ from 1900})$$

Especially, to reduce to -

1860,
$$\alpha = \alpha_0 + \frac{1}{10} c_0 + \frac{1}{200} s_0$$

1870, $\alpha = \alpha_0 + \frac{1}{5} c_0 + \frac{1}{50} s_0 + (\frac{1}{375} = 0.00266) \triangle s$
1875, $\alpha = \alpha_0 + \frac{1}{4} c_0 + \frac{1}{32} s_0 + (\frac{1}{192} = 0.0052) \triangle s$
1880, $\alpha = \alpha_0 + 0.3 c_0 + 0.045 s_0 + 0.0090 \triangle s$
1880, $\alpha = \alpha_1 - \frac{1}{5} c_1 + \frac{1}{50} s_1 - 0.00266 \triangle s$
1890, $\alpha = \alpha_1 - \frac{1}{10} c_1 + \frac{1}{200} s_1$

CLASS C.—Circumpolar stars.

Data given for 1755, 1800, 1850, 1900.

Let c_0 be the centennial variation.

 s_0 , the secular variation.

 Δ_0 , the mean first difference of s for 50 years for the catalogue epoch nearest that to which the star is to be reduced.

$$\alpha = \alpha_0 + T c_0 + \frac{1}{2} T^2 s_0 + \frac{1}{3} T^3 \triangle_0$$
For 5 years: $\alpha - \alpha_1 = \frac{1}{20} c_0 + \frac{1}{800} s_0 + \frac{1}{24000} \triangle$
For 10 years: $\alpha - \alpha_1 = \frac{1}{10} c_0 + \frac{1}{200} s_0 + \frac{1}{3000} \triangle_0$
For 15 years: $\alpha - \alpha_1 = 0.15 c_0 + 0.011 25 s_0 + 0.001 125 \triangle_0$
For 20 years: $\alpha - \alpha_1 = \frac{1}{5} c_0 + \frac{1}{50} s_0 + 0.002 67 \triangle_0$
For 25 years: $\alpha - \alpha_1 = \frac{1}{4} c_0 + 0.031 25 s_0 + 0.005 20 \triangle_0$

CLASS D.—Data for intervals of twenty-five years.

 \triangle'_0 the mean first difference for 25 years according to the scheme of differences given at the beginning of this section.

 \triangle_0'' the second difference for 25 years.

 $\triangle_0^{"}$ the mean third difference for 25 years.

Then, in general,

$$\alpha' = \alpha_0 + Tc_0 + \frac{1}{2}T^2s_0 + \frac{2}{3}T^3\Delta'_0 + \frac{2}{3}T^4\Delta''_0 + (\frac{8}{15}T^5 - \frac{1}{6}T^3)\Delta'''_0$$

Especially,

For — 10 years:

$$\alpha = \alpha_0 - \frac{1}{10}c_0 + \frac{1}{200}s_0 - \frac{1}{1500}\Delta'_0 + \frac{1}{15000}\Delta''_0 - 0.000 \text{ IO }\Delta'''_0$$

For -5 years:

$$\alpha = \alpha_0 - \frac{1}{20} c_0 + \frac{1}{800} s_0 - \frac{1}{12000} \Delta'_0 + \frac{1}{240000} \Delta''_0$$

For 5 years:

$$\alpha - \alpha_0 = \frac{1}{20} c_0 + \frac{1}{800} s_0 + \frac{1}{12000} \Delta_0' + \frac{1}{240000} \Delta_0''$$

For 10 years:

$$\alpha - \alpha_0 = \frac{1}{10} c_0 + \frac{1}{200} s_0 + \frac{1}{1500} \Delta'_0 + \frac{1}{15000} \Delta''_0 - 0.000 \text{ IO } \Delta'''_0$$

HILL'S FORMULÆ FOR THE SECULAR VARIATION OF THE ANNUAL MOTION AND PROPER MOTION OF THE STARS.

 μ , the centennial proper motion in R. A., expressed in seconds of time.

 μ' , the same in declination, expressed in seconds of arc.

p, p', the centennial precessions in R. A. and Dec. at any epoch, expressed in the same units as μ and μ' .

Then:

$$p = m + n \sin \alpha \tan \delta$$

$$p' = n \cos \alpha$$

$$\frac{d\alpha}{dT} = p + \mu$$

$$\frac{d\delta}{dT} = p' + \mu'$$

$$\frac{d^2\alpha}{dT^2} = + 0^8 \cdot 3^{22} - [6.6338] p + [7.9878] (p + 2 \mu) \cos \alpha \tan \delta + [6.8117] (p' + 2 \mu') \sin \alpha \sec^2 \delta + [4.9866] \mu \mu' \tan \delta$$

$$\frac{d^2\delta}{dT^2} = -[6.6338] p' - [9.1640] (p + 2 \mu) \sin \alpha - [6.7367] \mu^2 \sin 2 \delta$$

$$\frac{d\mu}{dT} = [7.9878] \mu \cos \alpha \tan \delta + [6.8117] \mu' \sin \alpha \sec^2 \delta + [4.9866] \mu \mu' \tan \delta$$

$$\frac{d\mu'}{dT} = -[9.1640] \mu \sin \alpha - [6.7367] \mu^2 \sin 2 \delta$$

ON

GAUSS'S METHOD

OF COMPUTING

SECULAR PERTURBATIONS,

WITH AN APPLICATION TO THE ACTION OF VENUS ON MERCURY.

BY

GEORGE W. HILL, ASSISTANT AMERICAN EPHEMERIS.

ON GAUSS'S METHOD OF COMPUTING SECULAR PERTURBATIONS.

In 1818 Gauss presented to the Royal Society of Sciences at Göttingen a memoir, the full title of which is Determinatio Attractionis quam in punctum quodvis positionis data exerceret planeta si ejus massa per totam orbitam ratione temporis quo singulæ partes describuntur uniformiter esset dispertita. (Werke, Band III, s. 331.)

This memoir is a notable one in the history of elliptic functions, as it contains a new algorithm for the computation of the complete functions of Legendre's first and second species. But we shall at present view it from the side of celestial mechanics. Gauss investigates the expressions for the components of the attraction of a certain species of elliptic ring on a point, which can be advantageously employed in computing the secular perturbations of a planet, at least the parts of them which are of the first order with respect to the disturbing forces. This method merits attention because, with it, we can secure almost absolute accuracy at the cost of a comparatively small outlay of labor. Moreover, it is capable of being applied, with success, to all the asteroids, and even to such refractory cases as the periodic comets. Yet, I can find but two published investigations where it has been employed. The first, a computation of the secular perturbations of the earth by Nicolai, results only being given (Berliner Astronomische Jahrbuch für 1820). The second, an application of the method to Tuttle's periodic comet by Dr. Thomas Clausen (Dorpater Beobachtungen, Band XVI, Einleitung). This, perhaps, is due to the circumstance that the memoir of Gauss does not contain all the formulæ needed in the application. A double integration being necessary, Gauss has considered only that in respect to the eccentric anomaly of the disturbing body, and, having regard to elegance only, has not reduced his equations to the forms giving the utmost brevity of calculation. Hence, I propose to give an exposition of the method with the additional formulæ required.

The following notation will be adopted: For the quantities pertaining to the disturbed planet, let

a denote the semi-axis major,

n " " mean motion in a Julian year,

e " " eccentricity,

 φ " angle of the eccentricity, such that $e = \sin \varphi$,

 π " longitude of the perihelion measured from a fixed equinox,

i " inclination of the orbit to a fixed ecliptic,

 Ω " longitude of the ascending node of the orbit on the fixed ecliptic,

L " mean longitude at the epoch,

χ " longitude of the perihelion measured from a point fixed in the shifting plane of the orbit,

317

 ω denote the angular distance of the perihelion from the ascending node $\equiv \pi - \Omega$,

r " radius vector,

M, E, r " mean, eccentric, and true anomalies,

u " argument of the latitude $= v + \omega$,

m " mass of the planet, the sun's being taken as the unit,

p " semi-parameter $\equiv a(1-e^2)$.

The similar quantities belonging to the disturbing planet will be denoted by the same letters accented. In addition, let R denote the component of the disturbing force in the direction of the radius vector, positive outward from the sun; S the component of the same perpendicular to the radius vector and in the plane of the orbit, positive in the direction of motion; and W the component perpendicular to the plane of the orbit, positive northward.

The differential equations, which give the variations of the elements of the disturbed planet, are

$$\frac{da}{dt} = \frac{2a^{3}n \sec \varphi}{1+m} \left[e \sin r \cdot R + \frac{p}{r} S \right]$$

$$\frac{de}{dt} = \frac{a^{2}n \cos \varphi}{1+m} \left[\sin r \cdot R + (\cos r + \cos E) S \right]$$

$$r \frac{d\chi}{dt} = \frac{a^{2}n \cos \varphi}{1+m} \left[-\cos r \cdot R + (\frac{r}{p} + 1) \sin r \cdot S \right]$$

$$\frac{di}{dt} = \frac{an \sec \varphi}{1+m} r \cos u \cdot W$$

$$\sin i \frac{d\Omega}{dt} = \frac{an \sec \varphi}{1+m} r \sin u \cdot W$$

$$\frac{d\pi}{dt} = \frac{d\chi}{dt} + 2 \sin^{2} \frac{i}{2} \cdot \frac{d\Omega}{dt}$$

$$\frac{dL}{dt} = -\frac{2an}{1+m} r \cdot R + 2 \sin^{2} \frac{\varphi}{2} \cdot \frac{d\chi}{dt} + 2 \sin^{2} \frac{i}{2} \cdot \frac{d\Omega}{dt} - \frac{3}{2} \int \frac{n \, da}{a \, dt} \, dt$$

where R, S, and W involve the factor $m' \equiv$ the mass of the disturbing planet measured with the sun's mass as the unit, but are not multiplied by the factor k^2 (k being usually known as the Gaussian constant).*

Provided the orbits do not intersect, and if we limit the approximation to terms of the first order with respect to the disturbing forces, each of these differential coefficients can be expanded in a periodic series of the form

$$\Sigma$$
. A $\frac{\sin}{\cos}(jM + j'M')$

j and j' being positive or negative integers, and A being constant. The term, for

^{*} For the proof of these formula the reader may consult either of the following sources: Encke, Berliner Astronomische Jahrbuch für 1837 und 1838, in the treatise Über die Berechnung der Speciellen Störungen, which has been reprinted in Encke's Abhandlungen; or Oppolzer, Lehrbuch zur Bahnbestimmung der Cometen und Planeten, Band II, s. 213 et seq.; or Watson, Theoretical Astronomy, pp. 516–523.

which both j = 0 and j' = 0, constitutes the secular portion of the series. The part of any differential coefficient, as $\frac{de}{dt}$, independent of M', is given by the definite integral

$$\frac{1}{2\pi} \int_0^{2\pi} \frac{de}{dt} dM'$$

and the secular portion, which is independent of both M and M', by the definite integral

$$\frac{1}{4\pi^2} \int_0^{2\pi} \int_0^{2\pi} \frac{de}{dt} dM dM'$$

But as we have the equations

$$d\mathbf{M} = \frac{r}{a} d\mathbf{E} = \frac{r^2}{a^2 \cos^2 \varphi} dv$$

$$d\mathbf{M}' \equiv \frac{r'}{a'} d\mathbf{E}' \equiv \frac{r'^2}{a'^2 \cos^2 \boldsymbol{\varphi}'} dv'$$

and as the variables M, E, and r all take the values o and 2π together, it is possible to make the integrations with reference to the eccentric or the true anomalies of the planets. Thus we have choice between four different procedures. That in which both of the integrations are executed with reference to the eccentric anomalies is to be preferred; for the inequalities of distribution of a series of points on an elliptic orbit, corresponding to equal intervals in the value of the eccentric anomaly, are of the order of the square of the eccentricity; while, for the other two anomalies, they are of the order of the first power of this quantity. Hence, to get the secular portion of the variation of any element, as e, we shall employ the double integral

$$\frac{1}{4\pi^2} \int_0^{2\pi} \int_0^{2\pi} \frac{de}{dt} \frac{r}{a} \frac{r'}{a'} dE dE'$$

the value of which we shall denote by $\begin{bmatrix} de \\ dt \end{bmatrix}_{m}$

As, in this method, the integration, with reference to E, will be performed by quadratures, instead of the notation

$$\frac{1}{2\pi} \int_0^{2\pi} X dE$$

we shall use M_E[X], which will denote the average of all the values of X with respect to the variable E. In the application of this method to the eight large planets of the solar system, the taking the average of 12 values, evenly distributed about the circumference with reference to E, will give, in all cases, extremely accurate results; and often 8 values will suffice. It can readily be shown, but, for the sake of brevity, we omit the demonstration, that, if the number of these values be even, the order of the error committed in the determination of the secular portions of the differential coeffi-

cients $\frac{de}{dt}$, $e\frac{d\pi}{dt}$, $\frac{di}{dt}$, and $\sin i\frac{d\Omega}{dt}$ will be the same as that of a power of the eccentricities or mutual inclination of orbits, whose exponent is one less than the number of these values, while the error, in the case of $\frac{dL}{dt}$, is of an order one degree higher. From this principle it can be judged, in any particular case, how many values ought to be computed.

It is well known that, not only when the approximation is limited to terms of the first order with respect to the disturbing forces, but even when terms of the second order are included, the secular portion of $\frac{da}{dt}$ vanishes. Hence, we can dispense with computing it.

If we put

$$R_{0} = \frac{1}{2\pi} \int_{0}^{2\pi} \frac{ar}{m'} R (1 - e' \cos E') dE'$$

$$S_{0} = \frac{1}{2\pi} \int_{0}^{2\pi} \frac{ar}{m'} S (1 - e' \cos E') dE'$$

$$W_{0} = \frac{1}{2\pi} \int_{0}^{2\pi} \frac{r^{2}}{m'} W (1 - e' \cos E') dE'$$

we shall have, for the secular portions of the differential coefficients of the elements of m, the equations

$$\begin{bmatrix} \frac{da}{dt} \end{bmatrix}_{00} = 0$$

$$\begin{bmatrix} \frac{de}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \cos \varphi. \, M_{E} \begin{bmatrix} \sin v. \, R_{0} + (\cos v + \cos E) \, S_{0} \end{bmatrix}$$

$$e \begin{bmatrix} \frac{d\chi}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \cos \varphi. \, M_{E} \begin{bmatrix} -\cos v. \, R_{0} + \left(\frac{r}{a \cos^{2} \varphi} + 1\right) \sin v. \, S_{0} \end{bmatrix}$$

$$\begin{bmatrix} \frac{di}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \sec \varphi. \, M_{E} \begin{bmatrix} \cos u. \, W_{0} \end{bmatrix}$$

$$\sin i \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \sec \varphi. \, M_{E} \begin{bmatrix} \sin u. \, W_{0} \end{bmatrix}$$

$$\begin{bmatrix} \frac{d\pi}{dt} \end{bmatrix}_{00} = \begin{bmatrix} \frac{d\chi}{dt} \end{bmatrix}_{00} + 2 \sin^{2} \frac{i}{2} \cdot \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00}$$

$$\begin{bmatrix} \frac{dL}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \, M_{E} \begin{bmatrix} -2\frac{r}{a} \, R_{0} \end{bmatrix} + 2 \sin^{2} \frac{\varphi}{2} \cdot \begin{bmatrix} \frac{d\chi}{dt} \end{bmatrix}_{00} + 2 \sin^{2} \frac{i}{2} \cdot \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00}$$

In the case of the earth, as the ecliptic is usually assumed as the plane of reference, at the epoch i vanishes and Ω is indeterminate. But this inconvenience is avoided by

substituting for i and Ω two variables p and q (where the reader is asked not to confound this p with the p which denotes the semi-parameter), such that

$$p \equiv \sin i \sin \Omega$$
 $q \equiv \sin i \cos \Omega$

When we shall have

$$\begin{bmatrix} \frac{dp}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \sec \varphi. M_{E} \begin{bmatrix} \sin (v+\pi). W_{0} \end{bmatrix}$$

$$\begin{bmatrix} \frac{dq}{dt} \end{bmatrix} = \frac{m'n}{1+m} \sec \varphi. M_{E} \begin{bmatrix} \cos (v+\pi). W_{0} \end{bmatrix}$$

The parts of R, S, and W, which arise from the action of the disturbing planet on the sun, have, in their periodic developments, no terms independent of M'. For

$$\int \frac{x'}{r'^3} dM' = -\frac{n'}{1+m'} \int \frac{d^2x'}{dt^2} dt = -\frac{n'}{1+m'} \frac{dx'}{dt}$$

which, as it has the same value for $M' \equiv 0$ and $M' \equiv 2\pi$, leads to

$$\int_0^{2\pi} \frac{x'}{r'^3} d\mathbf{M}' = 0$$

In like manner

$$\int_{0}^{2\pi} \frac{y'}{r'^{3}} dM' = 0 \qquad \int_{0}^{2\pi} \frac{z'}{r'^{3}} dM' = 0$$

Hence, for our present purpose, it will suffice to consider only the mutual action of the two planets. Then, assuming a system of rectangular co-ordinates, two of whose axes, x and y, lie in the plane of the orbit of the disturbed planet, so that z = 0, R, S, and W are determined by the equations

$$r \atop m' R = \frac{xx' + yy' - r^2}{\triangle^3}$$

$$r \atop m' S = \frac{xy' - x'y}{\triangle^3}$$

$$r \atop M' W = \frac{z'}{\triangle^3}$$

and the distance \triangle of the two planets by the equation

$$\triangle^2 = r^2 - 2(xx' + yy') + r'^2$$

In order to accomplish the integrations which R_0 , S_0 , and W_0 involve, it will be necessary to express R, S, and W explicitly in terms of the variable E'. If I denotes the mutual inclination of the orbits, and Π and Π' severally the angular distances of

the perihelia from the ascending node of the orbit of the disturbing planet on the orbit of the disturbed, these quantities are determined by the equations

$$\sin I \cos (II - \omega) \equiv -\sin i \cos i' + \cos i \sin i' \cos (\Omega' - \Omega)$$

$$\sin I \sin (II - \omega) \equiv -\sin i \cos i' \sin (\Omega' - \Omega)$$

$$\sin I \cos (II' - \omega') \equiv \cos i \sin i' - \sin i \cos i' \cos (\Omega' - \Omega)$$

$$\sin I \sin (II' - \omega') \equiv -\sin i \sin i (\Omega' - \Omega)$$

We shall then have

$$xx' + yy' = rr' \left[\cos(v + II)\cos(v' + II') + \cos I\sin(v + II)\sin(v' + II') \right]$$

 $xy' - x'y = rr' \left[-\sin(v + II)\cos(v' + II') + \cos I\cos(v + II)\sin(v' + II') \right]$
 $z' = r'\sin I\sin(v' + II')$

But if four auxiliary constants, k, K, k', and K', are so taken that

$$k \cos (K - II) \equiv \cos II'$$
 $k' \cos (K' - II) \equiv \cos I \cos II'$
 $k \sin (K - II) \equiv -\cos I \sin II'$ $k' \sin (K' - II) \equiv -\sin II'$

the first two equations take the forms

$$xx' + yy' \equiv kr\cos(v + K). r'\cos v' + k'r\sin(v + K'). r'\sin v'$$
$$xy' - x'y \equiv -kr\sin(v + K). r'\cos v' + k'r\cos(v + K'). r'\sin v'$$

By the substitution of the values

$$r' \cos r' \equiv a' (\cos E' - e)$$
 $r' \sin v' \equiv a' \cos \varphi' \sin E'$

we have

$$xx' + yy' \equiv ka'r\cos(r + K) (\cos E' - e') + k'a'\cos\varphi'. r\sin(v + K')\sin E'$$

$$xy' - x'y \equiv -ka'r\sin(v + K) (\cos E' - e') + k'a'\cos\varphi'. r\cos(v + K')\sin E'$$

$$z' \equiv a'\sin I\sin II' (\cos E' - e') + a'\sin I\cos\Pi'\cos\varphi'\sin E'$$

Moreover,

$$r' \equiv a' (1 - e' \cos \mathbf{E}')$$

in consequence, if we put

$$\Lambda = r^{2} + 2 ka'e'r \cos(r + K) + a'^{2}$$

$$B \cos \epsilon = ka'r \cos(r + K) + a'^{2}e'$$

$$B \sin \epsilon = k'a' \cos \varphi'. r \sin(r + K')$$

$$C = a'^{2}e'^{2}$$

we shall have

$$\triangle^2 = A - 2B\cos(E' - \epsilon) + C\cos^2 E'$$

R, S, and W are now expressed explicitly in terms of E'. Gauss's method of

effecting the integrations, which give R_0 , S_0 , and W_0 , consists in taking a new variable T, such that

$$\cos E' = \frac{\alpha + \alpha' \sin T + \alpha'' \cos T}{\gamma + \gamma' \sin T + \gamma'' \cos T}$$

$$\sin E' = \frac{\beta + \beta'}{\gamma + \gamma'} \frac{\sin T + \beta''}{\sin T + \gamma''} \frac{\cos T}{\cos T}$$

where α , β , γ , &c, satisfy certain conditions, and, moreover, are so taken that the coefficients of sin T, cos T and sin T cos T vanish in the expression

$$\triangle^2 \left[\gamma + \gamma' \sin T + \gamma'' \cos T \right]^2$$

which, in consequence, takes the form

$$G - G'\sin^2 T + G''\cos^2 T$$

As the equation

 $[\alpha + \alpha' \sin T + \alpha'' \cos T]^2 + [\beta + \beta' \sin T + \beta'' \cos T]^2 - [\gamma + \gamma' \sin T + \gamma'' \cos T]^2 = 0$ ought to hold true independently of the value of T, the left member must have the form

$$k \left(\sin^2 T + \cos^2 T - 1\right)$$

but as it is plain that the values of α , α' , &c., can be multiplied by a common factor without any change resulting in sin E' and cos E', we may assume $k \equiv 1$. We then have the six equations of condition

$$\alpha^{2} + \beta^{2} - \gamma^{2} = -1$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 1$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 1$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 1$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

$$\alpha^{2} + \beta^{2} - \gamma^{2} = 0$$

From the values of sin E' and cos E' in terms of T, by having regard to the equations of condition just written, we obtain

$$\alpha \cos E' + \beta \sin E' - \gamma = \frac{-1}{\gamma + \gamma' \sin T + \gamma'' \cos T}$$

$$\alpha' \cos E' + \beta' \sin E' - \gamma' = \frac{\sin T}{\gamma + \gamma' \sin T + \gamma'' \cos T}$$

$$\alpha'' \cos E' + \beta'' \sin E' - \gamma'' = \frac{\cos T}{\gamma + \gamma' \sin T + \gamma'' \cos T}$$

Hence, as the equation

 $[\alpha \cos E' + \beta \sin E' - \gamma]^2 - [\alpha' \cos E' + \beta' \sin E' - \gamma']^2 - [\alpha'' \cos E' + \beta'' \sin E' - \gamma'']^2 = 0$ ought to be satisfied independently of the value assigned to E', the left member must have the form

$$k \left[\sin^2 \mathbf{E}' + \cos^2 \mathbf{E}' - 1 \right]$$

Consequently,

$$\alpha^{2} - \alpha'^{2} - \alpha''^{2} \equiv k \qquad \alpha\beta - \alpha'\beta' - \alpha''\beta'' \equiv 0$$

$$\beta^{2} - \beta'^{2} - \beta''^{2} \equiv k \qquad \alpha\gamma - \alpha'\gamma' - \alpha''\gamma'' \equiv 0$$

$$\gamma^{2} - \gamma'^{2} - \gamma''^{2} \equiv -k \qquad \beta\gamma - \beta'\gamma' - \beta''\gamma'' \equiv 0$$

But by comparing the three of these equations which involve squares of the quantities α , α' , &c., with the similar three of the equations of condition previously obtained, we get 3k = -3, or k = -1.

The six equations of condition first obtained may be so written as to form three groups of linear equations, thus:

$$\alpha. \quad \alpha+\beta. \quad \beta-\gamma. \quad \gamma=-1 \qquad \alpha. \quad \alpha'+\beta. \quad \beta'-\gamma. \quad \gamma'=0 \qquad \alpha. \quad \alpha''+\beta. \quad \beta''-\gamma. \quad \gamma''=0$$

$$\alpha'. \quad \alpha+\beta'. \quad \beta-\gamma'. \quad \gamma=0 \qquad \alpha'. \quad \alpha'+\beta'. \quad \beta'-\gamma'. \quad \gamma'=1 \qquad \alpha'. \quad \alpha''+\beta'. \quad \beta''-\gamma'. \quad \gamma''=0$$

$$\alpha''. \quad \alpha+\beta''. \quad \beta-\gamma''. \quad \gamma=0 \qquad \alpha''. \quad \alpha'+\beta''. \quad \beta''-\gamma''. \quad \gamma''=1$$

If we put

$$D = \alpha \beta' \gamma'' - \alpha' \beta \gamma'' + \alpha' \beta'' \gamma - \alpha'' \beta' \gamma + \alpha'' \beta \gamma' - \alpha \beta'' \gamma'$$

we shall have

$$D\alpha = -\frac{dD}{d\alpha} = \beta''\gamma' - \beta'\gamma''$$

$$D\alpha' = -\frac{dD}{d\alpha'} = \beta''\gamma - \beta\gamma''$$

$$D\beta' = -\frac{dD}{d\beta'} = \alpha\gamma'' - \alpha''\gamma'$$

$$D\beta' = -\frac{dD}{d\beta'} = \alpha\gamma'' - \alpha''\gamma'$$

$$D\gamma' = -\frac{dD}{d\gamma'} = \alpha\beta'' - \alpha''\beta'$$

$$D\alpha'' = -\frac{dD}{d\alpha''} = \beta\gamma' - \beta\gamma'$$

$$D\beta'' = -\frac{dD}{d\beta''} = \alpha\gamma' - \alpha\gamma'$$

$$D\gamma'' = -\frac{dD}{d\gamma''} = \alpha\beta' - \alpha\beta'$$

The value of D may be found by taking any one of the twelve preceding equations of condition between α , α' , &c., and substituting in it the values of α , α' , &c., from the preceding nine equations. Thus, if we take the equation

$$\alpha^2 - \alpha'^2 - \alpha''^2 - - 1$$

we shall have

$$D^{2} (-\alpha^{2} + \alpha'^{2} + \alpha''^{2}) = D^{2} = (\beta \gamma' - \beta' \gamma)^{2} + (\beta'' \gamma - \beta \gamma'')^{2} - (\beta' \gamma'' - \beta'' \gamma')^{2}$$

$$= \beta^{2} \gamma'^{2} + \beta'^{2} \gamma^{2} + \beta''^{2} \gamma^{2} + \beta^{2} \gamma''^{2} - \beta'^{2} \gamma''^{2} - \beta''^{2} \gamma'^{2}$$

$$- 2 \beta \gamma \beta' \gamma' - 2 \beta \gamma \beta'' \gamma'' + 2 \beta' \gamma' \beta'' \gamma''$$

$$= \beta^{2} (\gamma^{2} - 1) + \beta'^{2} (\gamma'^{2} + 1) + \beta''^{2} (\gamma''^{2} + 1)$$

$$- 2 \beta \gamma \beta' \gamma' - 2 \beta \gamma \beta'' \gamma'' + 2 \beta' \gamma' \beta'' \gamma''$$

$$= - \beta^{2} + \beta'^{2} + \beta''^{2} + (\beta \gamma - \beta' \gamma' - \beta'' \gamma'')^{2}$$

$$= 1$$

Hence, $D = \pm 1$. It is evident we may adopt either sign, consequently we take the positive one.

The foregoing equations between the quantities α , α' , &c., are all that are necessary for our purposes, but in order to obtain the values of these quantities and also of the three G, G', and G'' we must have recourse to the equations furnished by the transformation of the expression for Δ^2 . This transformation evidently comes to the same thing as the changing of the expression

$$Az^2 - 2B\cos \varepsilon$$
. $xz - 2B\sin \varepsilon$. $yz + Cx^2$

into

$$Gu^2 - G'u'^2 + G''u''^2$$

by the employment of the formulæ

$$x = \alpha u + \alpha' u' + \alpha'' u''$$

$$y = \beta u + \beta' u' + \beta'' u''$$

$$z = \gamma u + \gamma' u' + \gamma'' u''$$

But, having regard to the equations which the quantities α , α' , &c., satisfy, we readily deduce from the last-given equations

$$u = -\alpha x - \beta y + \gamma z$$

$$u' = \alpha' x + \beta' y - \gamma' z$$

$$u'' = \alpha'' x + \beta'' y - \gamma'' z$$

By substitution of these values in the expression $Gu^2 - G'u'^2 + G''u''^2$ and comparison of the resulting coefficients with

$$Az^2 - 2B\cos \epsilon$$
. $xz - 2B\sin \epsilon$. $yz + Cx^2$

we get the following equations:

$$G\alpha^{2} - G'\alpha'^{2} + G''\alpha''^{2} \equiv C$$

$$G\alpha\beta - G'\alpha'\beta' + G''\alpha''\beta'' \equiv 0$$

$$G\alpha\beta - G'\alpha'\beta' + G''\alpha''\beta'' \equiv 0$$

$$G\alpha\gamma - G'\alpha'\gamma' + G''\alpha''\gamma'' \equiv B\cos\varepsilon$$

$$G\gamma^{2} - G'\gamma'^{2} + G''\gamma''^{2} \equiv A$$

$$G\beta\gamma - G'\beta'\gamma' + G''\beta''\gamma'' \equiv B\sin\varepsilon$$

which, in conjunction with the six independent equations between α , α' , &c., previously obtained, suffice to determine the twelve unknowns, α , α' , α'' , β , β' , β'' , γ , γ''

These six equations can be written in three groups of three equations each, the first group being as follows:

$$\alpha$$
. $G\alpha - \alpha'$. $G'\alpha' + \alpha''$. $G''\alpha'' \equiv C$
 α . $G\beta - \alpha'$. $G'\beta' + \alpha''$. $G''\beta'' \equiv o$
 α . $G\gamma - \alpha'$. $G'\gamma' + \alpha''$. $G''\gamma'' \equiv B\cos \varepsilon$

The second and third groups are obtained from this by writing in succession β and γ for α in the first factors of the terms of the left members of the equations, and

making the second members, in the first case, severally 0, 0, and B sin ε , and in the second, B cos ε , B sin ε , and A. By having regard to the six equations of conditions between α , α' , &c., which were first obtained, we get from these three groups severally the following three groups of equations:

$$\begin{cases}
G\alpha &=- C\alpha + B \cos \varepsilon. \gamma \\
G\beta &= B \sin \varepsilon. \gamma \\
G\gamma &=- B \cos \varepsilon. \alpha - B \sin \varepsilon. \beta + A\gamma
\end{cases}$$

$$\begin{cases}
G'\alpha' &=- C\alpha' + B \cos \varepsilon. \gamma' \\
G'\beta' &= B \sin \varepsilon. \gamma' \\
G'\gamma' &=- B \cos \varepsilon. \alpha' - B \sin \varepsilon. \beta' + A\gamma'
\end{cases}$$

$$\begin{cases}
-G''\alpha'' &=- C\alpha'' + B \cos \varepsilon. \gamma'' \\
-G''\beta'' &= B \sin \varepsilon. \gamma'' \\
-G''\gamma'' &=- B \cos \varepsilon. \alpha'' - B \sin \varepsilon. \beta'' + A\gamma''
\end{cases}$$

From the first two equations of each of these three groups is obtained

$$\alpha = \frac{B \cos \varepsilon}{G + C} \gamma \qquad \qquad \alpha' = \frac{B \cos \varepsilon}{G' + C} \gamma' \qquad \qquad \alpha'' = \frac{B \cos \varepsilon}{C - G''} \gamma''$$

$$\beta = \frac{B \sin \varepsilon}{G} \gamma \qquad \qquad \beta' = \frac{B \sin \varepsilon}{G'} \gamma' \qquad \qquad \beta'' = -\frac{B \sin \varepsilon}{G''} \gamma''$$

By substituting these values of α , β , &c., in the last equation of each group we obtain

$$G - A + \frac{B^2 \cos^2 \varepsilon}{G + C} + \frac{B^2 \sin^2 \varepsilon}{G} = 0$$

$$G' - A + \frac{B^2 \cos^2 \varepsilon}{G' + C} + \frac{B^2 \sin^2 \varepsilon}{G'} = 0$$

$$-G'' - A + \frac{B^2 \cos^2 \varepsilon}{-G'' + C} + \frac{B^2 \sin^2 \varepsilon}{-G''} = 0$$

It is evident, now, that G, G', and -G'' are the roots of the cubic equation

$$x - A + \frac{B^2 \cos^2 \varepsilon}{x + C} + \frac{B^2 \sin^2 \varepsilon}{x} = 0$$

or of

$$x \left[(x - A) (x + C) + B^2 \right] + B^2 \sin^2 \varepsilon = 0$$

The roots of this equation are all real, as can be shown in the following manner: If, for the moment, we adopt Gauss's system of rectangular co-ordinates, that is, put the origin at the center of the ellipse described by the disturbing planet, and make the axes of x and y coincide severally with the major and minor axes of this ellipse, and suppose that the co-ordinates of the disturbed planet, with reference to this system of

axes are denoted by A, B, and C, the expression for \triangle^2 , which, in our notation, is

$$\triangle^2 = A - 2B \cos(E' - \epsilon) + C \cos^2 E'$$

will become

$$\Delta^{2} = (A - a' \cos E')^{2} + (B - a' \cos \varphi' \sin E') + C^{2}$$

$$= A^{2} + B^{2} + C^{2} + a'^{2} \cos^{2} \varphi' - 2 (Aa' \cos E' + Ba' \cos \varphi' \sin E') + a'^{2} \sin^{2} \varphi' \cos^{2} E'$$

By comparison of these two expressions for \triangle^2 , we find that, expressed in terms of the second system of co-ordinates, the equation in x becomes

$$x \left[x - (A^2 + B^2 + C^2 + a'^2 \cos^2 \varphi') \right] (x + a'^2 \sin^2 \varphi') + (A^2 a'^2 + B^2 a'^2 \cos^2 \varphi') x + B^2 a'^4 \sin^2 \varphi' \cos^2 \varphi' = 0$$

We substitute for x in this equation the four values — C, o, $a'^2 \cos^2 \varphi'$, and A, and obtain the results

$$x = -a^{\prime 2} \sin^2 \varphi' = -C$$
 result, $-A^2 a^{\prime 4} \sin^2 \varphi'$
 $x = 0$ " $+B^2 a^{\prime 4} \sin^2 \varphi' \cos^2 \varphi'$
 $x = a^{\prime 2} \cos^2 \varphi'$ " $-C^2 a^{\prime 4} \cos^2 \varphi'$
 $x = A$ " $+B^2 (A + C \sin^2 \varepsilon)$

From this it is apparent that the roots are all real, one being negative and numerically less than C, one positive and less than $a'^2 \cos^2 \varphi'$, and another positive and lying between $a'^2 \cos^2 \varphi'$ and A.

The assignment of these roots as the values of G, G', and -G'' is not indifferent; as we wish both Δ and the transformation to be real, we put G equal to the larger of the positive roots, G' equal to the smaller, and -G'' equal to the negative root. Consequently, G, G', and G'' are always positive quantities.

The readiest method of obtaining them from the equation of the third degree, which determines them, appears to be by trial. If we put

$$g = B^{2} C \sin^{2} \varepsilon$$

 $h = \frac{1}{2} [A - C + \sqrt{(A+C)^{2} - 4B^{2}}]$
 $l = \frac{1}{2} [A - C - \sqrt{(A+C)^{2} - 4B^{2}}]$

the equation takes the form

$$x(x-h)(x-l)+g=0$$

As g is usually a small quantity, having the factor e'^2 , the approximate values of the roots are o, l, and h. G, G', and G'' can then be obtained, by successive approximations, from the equation put in the forms

$$G = h - \frac{g}{G(G - l)}$$

$$G' = l + \frac{g}{G'(h - G')}$$

$$G'' = \frac{g}{(h + G'')(l + G'')}$$

quite approximate values being

$$G = h - \frac{g}{h(h-l)} \qquad G' = l + \frac{g}{l(h-l)} \qquad G'' = \frac{g}{\left(h + \frac{g}{hl}\right)\left(l + \frac{g}{hl}\right)}$$

For verification we may employ either or both of the equations

$$G + G' - G'' = A - C$$

 $GG'G'' = B^2C \sin^2 \varepsilon$

It will be seen that, in order to make our desired transformation from the variable E' to the variable T, we do not need the values of the nine quantities α , α' , &c., but only the values of the following ten squares and products of them, viz, α'^2 , γ'^2 , $\alpha'\beta'$, $\alpha'\gamma'$, $\beta'\gamma'$, α''^2 , γ''^2 , $\alpha''\beta''$, and $\beta''\gamma''$; hence, we will limit ourselves to the determination of these.

The values of α' and β' , in terms of γ' , and of α'' and β'' , in terms of γ'' , have already been given. If we substitute them in the equations

$$\alpha'^2 + \beta'^2 - \gamma'^2 = 1$$
 $\alpha''^2 + \beta''^2 - \gamma''^2 = 1$

we obtain

$$\begin{bmatrix} \frac{B^2 \cos^2 \varepsilon}{(G' + C)^2} + \frac{B^2 \sin^2 \varepsilon}{G'^2} - 1 \end{bmatrix} \gamma' = 1$$

$$\begin{bmatrix} \frac{B^2 \cos^2 \varepsilon}{(C - G'')^2} + \frac{B^2 \sin^2 \varepsilon}{G''^2} - 1 \end{bmatrix} \gamma'' = 1$$

Whence

$$\gamma^{\prime 2} = \frac{\frac{(G' + C) G'}{B^2 \cos^2 \varepsilon}}{\frac{B^2 \cos^2 \varepsilon}{G' + C} G' + \frac{B^2 \sin^2 \varepsilon}{G'} (G' + C) - (G' + C) G'}$$

or having regard to the equation which determines G',

$$\gamma'^{2} = \frac{(G' + C) G'}{(A - G') G' + \frac{B^{2}C \sin^{2} \varepsilon}{G'} - (G' + C) G'}$$

$$= \frac{(G' + C) G'}{(A - C - 2G') G' + GG''}$$

$$= \frac{(G' + C) G'}{(G' + G'') (G - G')}$$

And in like manner,

$$\begin{split} \gamma''^2 &= \frac{(C - G'') G''}{\frac{B^2 \cos^2 \varepsilon}{C - G''} G'' + \frac{B^2 \sin^2 \varepsilon}{G''} (C - G'') - (C - G'') G''} \\ &= \frac{(C - G'') G''}{(A + G'') G'' + GG' - (C - G'') G''} \\ &= \frac{(C - G'') G''}{(G + G'') (G' + G'')} \end{split}$$

We have

$$\frac{B^2}{G'} \frac{\cos^2 \varepsilon}{+C} = A - G' - \frac{B^2}{G'} \frac{\sin^2 \varepsilon}{G'}$$

consequently,

$$\alpha'^2 = \frac{(A - G') G' - B^2 \sin^2 \varepsilon}{(G' + G'') (G - G'')}$$

Also,

$$\frac{B^2 \cos^2 \varepsilon}{C - G''} = A + G'' + \frac{B^2 \sin^2 \varepsilon}{G''}$$

consequently,

$$\alpha^{\prime\prime 2} = \frac{(A + G^{\prime\prime}) G^{\prime\prime} + B^2 \sin^2 \varepsilon}{(G + G^{\prime\prime}) (G^{\prime} + G^{\prime\prime})}$$

And the values of the six products needed are

$$\alpha'\beta' = \frac{B^2 \sin \varepsilon \cos \varepsilon}{(G' + G'')(G - G')}$$

$$\alpha''\beta'' = -\frac{B^2 \sin \varepsilon \cos \varepsilon}{(G + G'')(G' + G'')}$$

$$\alpha'\gamma' = \frac{B \cos \varepsilon \cdot G'}{(G' + G'')(G - G')}$$

$$\alpha''\gamma'' = \frac{B \cos \varepsilon \cdot G''}{(G + G'')(G' + G'')}$$

$$\beta''\gamma'' = -\frac{B \sin \varepsilon \cdot (C + G')}{(G + G'')(G' + G'')}$$

We have next to ascertain the value of the differential dE' in terms of the differential dT. From the equations

H cos E'
$$\equiv \alpha + \alpha' \sin T + \alpha'' \cos T$$

H sin E' $\equiv \beta + \beta' \sin T + \beta'' \cos T$

where H stands for $\gamma + \gamma' \sin E' + \gamma'' \cos E'$, it follows that

$$\mathrm{H} \ d\mathrm{E}' = [\cos \mathrm{E}' \ (\beta' \ \cos \mathrm{T} - \beta'' \ \sin \mathrm{T}) - \sin \mathrm{E}' \ (\alpha' \ \cos \mathrm{T} - \alpha'' \ \sin \mathrm{T})] \ d\mathrm{T}$$

or

$$H^{2} dE' = [(\alpha''\beta' - \alpha'\beta'') + (\alpha''\beta - \alpha\beta'') \sin T + (\alpha\beta' - \alpha'\beta) \cos T] dT$$
$$= -[\gamma + \gamma' \sin T + \gamma'' \cos T] dT$$

Whence

$$H dE' = -dT$$

The quantity H is always of the same sign, otherwise sin E' and cos E' might become infinite in the passage of H through zero. If this consideration is not deemed conclusive, the point can be established as follows:

Since we have

$$(\gamma' \sin T + \gamma'' \cos T)^2 + (\gamma'' \sin T - \gamma' \cos T)^2 = \gamma'^2 + \gamma''^2 = \gamma^2 - 1$$

without regard to signs, $\gamma' \sin T + \gamma'' \cos T$ will always be less than γ . Hence, if γ be negative, T will always increase when E' increases; but if γ be positive, T will always diminish when E' increases.

If we put $\sqrt{\gamma^2 - 1} = \delta$, so that $\delta^2 = \alpha^2 + \beta^2 = \gamma'^2 + \gamma''^2$, we shall have

H
$$(\delta + \alpha \cos E' + \beta \sin E') = \gamma \delta + \alpha^2 + \beta^2 + (\gamma' \delta + \alpha \alpha' + \beta \beta') \sin T + (\gamma'' \delta + \alpha \alpha'' + \beta \beta'') \cos T$$

= $(\gamma + \delta) (\delta + \gamma' \sin T + \gamma'' \cos T)$

Also,

H
$$(\alpha \sin E' - \beta \cos E') \equiv (\alpha \beta' - \alpha' \beta) \sin T + (\alpha \beta'' - \alpha'' \beta) \cos T$$

= $\gamma'' \sin T - \gamma' \cos T$

By putting

$$\frac{\alpha}{\delta} = \cos L$$
 $\frac{\beta}{\delta} = \sin L$ $\frac{\gamma''}{\delta} = \cos M$ $\frac{\gamma'}{\delta} = \sin M$

these two equations become

$$H[I + \cos(E' - L)] = (\gamma + \delta)[I + \cos(T - M)]$$

$$H \sin(E' - L) = \sin(T - M)$$

By division we get

$$\tan \frac{1}{2} (T - M) = (\gamma + \delta) \tan \frac{1}{2} (E' - L)$$

From this equation it is evident that, when E' augments by a circumference, T augments or diminishes by the same quantity according as γ is negative or positive.

The expressions we have to integrate with respect to E' are of the form $\frac{\Theta}{\triangle^3}$; hence, whether γ be positive or negative, we shall always have

$$\int_0^{2\pi} \frac{\Theta}{\Delta^3} dE' = \int_0^{2\pi} \frac{H^2 \Theta}{(H^2 \Delta^2)_2^3} dT$$

provided that we understand that the radical in the denominator is to have the positive sign.

The general form of Θ is

$$\Theta = [f + g(\cos E' - e') + h \sin E'] (1 - e' \cos E')$$

$$= f - ge' + [g(1 + e'^2) - fe'] \cos E' + h \sin E' - he' \sin E' \cos E' - ge' \cos^2 E'$$

If in this expression, multiplied by H^2 , are substituted the values of H^2 , $H \cos E'$, and $H \sin E'$ in terms of T, and the terms multiplied by $\sin T$, $\cos T$, and $\sin T \cos T$ omitted, as, when integrated between the limits o and 2π they contribute nothing to the value of the integral, we get

$$\begin{aligned} H^{2}\Theta &= (f - ge') \; (\gamma^{2} + \gamma'^{2} \sin^{2} T + \gamma''^{2} \cos^{2} T) \\ &+ [g \; (1 + e'^{2}) - fe'] \; (\alpha \gamma + \alpha' \gamma' \sin^{2} T + \alpha'' \gamma'' \cos^{2} T) \\ &+ h \; (\beta \gamma + \beta' \gamma' \sin^{2} T + \beta'' \gamma'' \cos^{2} T) \\ &- he' \; (\alpha \beta + \alpha' \beta' \sin^{2} T + \alpha'' \beta'' \cos^{2} T) \\ &- ge' \; (\alpha^{2} + \alpha'^{2} \sin^{2} T + \alpha''^{2} \cos^{2} T) \end{aligned}$$

But we have the equations

$$\alpha^{2} = -1 + \alpha'^{2} + \alpha''^{2}$$

$$\gamma^{2} = 1 + \gamma'^{2} + \gamma''^{2}$$

$$\alpha\beta = \alpha'\beta' + \alpha''\beta''$$

$$\alpha\gamma = \alpha'\gamma' + \alpha''\gamma''$$

$$\beta\gamma = \beta'\gamma' + \beta''\gamma''$$

Hence, if we put

$$\begin{split} \Gamma' &= (f - ge') \ \gamma'^2 + [g \ (\mathbf{1} + e'^2) - fe'] \ \alpha' \gamma' \ + h \beta' \gamma' \ - h e' \alpha' \beta' \ - g e' \alpha'^2 \\ \Gamma'' &= (f - ge') \ \gamma''^2 + [g \ (\mathbf{1} + e'^2) - fe'] \ \alpha'' \gamma'' + h \beta'' \gamma'' - h e' \alpha'' \beta'' - g e' \alpha''^2 \end{split}$$

we shall have

$$H^2\Theta \equiv [2\Gamma' + \Gamma'' + f] \sin^2 \Gamma + [\Gamma' + 2\Gamma'' + f] \cos^2 \Gamma$$

If we substitute, in the expressions for Γ' and Γ'' , for γ'^2 , $\alpha'\gamma'$, &c., the values we have previously obtained for these squares and products, and, moreover, put

F =
$$[ge' B \sin \varepsilon - he' B \cos \varepsilon + hC] B \sin \varepsilon$$

J = $-ge' A + (f - ge') C + [g(1 + e'^2) - fe'] B \cos \varepsilon + hB \sin \varepsilon$

we shall obtain

$$\Gamma' = \frac{F + JG' + fG'^2}{(G' + G'')(G - G')} \qquad \qquad \Gamma'' = \frac{-F + JG'' - fG''^2}{(G + G'')(G' + G'')}$$

Substituting in the values of F and J the values of A, B cos ϵ , B sin ϵ , and C, we get

$$F = a'e'r \text{ B sin } \varepsilon \left[gk' \cos \varphi' \sin \left(v + \mathbf{K}' \right) - hk \cos \left(v + \mathbf{K} \right) \right]$$

$$J = -fa'e'kr \cos \left(v + \mathbf{K} \right) + g \left[ka' \cos^2 \varphi' \cdot r \cos \left(v + \mathbf{K} \right) - e'r^2 \right]$$

$$+ hk'a' \cos \varphi' \cdot r \sin \left(v + \mathbf{K}' \right)$$

To apply these formulæ to the three special cases of the computation of R_0 , S_0 , and W_0 . In the case of R_0 we have

$$f = -ar^2$$
 $g = kaa'r \cos(v + K)$ $h = k'aa' \cos \varphi'$. $r \sin(v + K')$

Consequently, here

F = 0
J =
$$aa'^2 \cos^2 \varphi'$$
. $r^2 [k^2 \cos^2 (v + K) + k'^2 \sin^2 (v + K')]$
= $aa'^2 \cos^2 \varphi'$. $r^2 [1 - \sin^2 I \sin^2 (v + II)]$

In the case of S₀ we have

$$f = 0$$
 $g = -kaa'r \sin(v + K)$ $h = k'aa' \cos \varphi'$. $r \cos(v + K')$

Consequently, here

$$F = -aa'^{2} kk' \cos (K' - K) \sin \varphi' \cos \varphi'. r^{2} B \sin \varepsilon$$

$$= -aa'^{2} \sin \varphi' \cos \varphi' \cos I. r^{2} B \sin \varepsilon$$

$$J = kaa'e'r^{2} \sin (v + K) + \frac{1}{2} aa'^{2} \cos^{2} \varphi'. r^{2} [k'^{2} \sin 2 (v + K') - k^{2} \sin 2 (v + K)]$$

$$= kaa'e'r^{3} \sin (v + K) - \frac{1}{2} aa'^{2} \cos^{2} \varphi' \sin^{2} I. r^{2} \sin 2 (v + II)$$

In the case of Wo we have

$$f \equiv 0$$
 $g \equiv a' \sin I \sin \Pi'$. r^2 $h \equiv a' \sin I \cos \Pi' \cos \varphi'$. r^2

Consequently, here

$$\begin{aligned} \mathbf{F} &= a'^2 \sin \varphi' \cos \varphi' \sin I. \ r^3 \, \mathbf{B} \sin \varepsilon \left[k' \sin \Pi' \sin \left(v + \mathbf{K}' \right) - k \cos \Pi' \cos \left(v + \mathbf{K} \right) \right] \\ &= -a'^2 \sin \varphi' \cos \varphi' \sin I. \ r^3 \cos \left(v + \Pi \right). \ \mathbf{B} \sin \varepsilon \\ \mathbf{J} &= a'^2 \cos^2 \varphi' \sin I. \ r^3 \left[k \sin \Pi' \cos \left(v + \mathbf{K} \right) + k' \cos \Pi' \sin \left(v + \mathbf{K}' \right) \right] \\ &- a' \sin \varphi' \sin I \sin \Pi'. \ r^4 \\ &= a'^2 \cos^2 \varphi' \sin I \cos I. \ r^3 \sin \left(v + \Pi \right) - a'c' \sin I \sin \Pi'. \ r^4 \end{aligned}$$

The values of R₀, S₀, and W₀ are given by the definite integral

$$\frac{1}{2\pi} \int_{0}^{2\pi} \frac{\left[2\Gamma' + \Gamma'' + f\right] \sin^{2} \Gamma + \left[\Gamma' + 2\Gamma'' + f\right] \cos^{2} \Gamma}{\left[G + G''\right]^{\frac{3}{2}} \left[1 - c^{2} \sin^{2} \Gamma\right]^{\frac{3}{2}}} d\Gamma$$

provided we attribute to F, J, and f the values they have in each case. In this expression we have put

$$\frac{G' + G''}{G + G''} = c^2$$

c is then the modulus of the elliptic integrals involved in the expression. Let b denote the complementary modulus $= \sqrt{1 - c^2}$. In the notation of Legendre

$$\int_{0}^{\frac{\pi}{2}} \frac{d\mathbf{T}}{[\mathbf{I} - c^{2} \sin^{2} \mathbf{T}]^{\frac{1}{2}}} = \mathbf{F}^{1} (c) \qquad \int_{0}^{\frac{\pi}{2}} [\mathbf{I} - c^{2} \sin^{2} \mathbf{T}]^{\frac{1}{2}} d\mathbf{T} = \mathbf{E}^{1} (c)$$

We have the equation

$$\frac{d}{dT} \frac{\sin T \cos T}{[1-c^2 \sin^2 T]^{\frac{1}{2}}} = \frac{1-2 \sin^2 T + c^2 \sin^4 T}{[1-c^2 \sin^2 T]^{\frac{3}{2}}}$$

whence

$$\int_{0}^{\frac{\pi}{2}} \frac{1 - 2 \sin^{2} T + c^{2} \sin^{4} T}{[1 - c^{2} \sin^{2} T]^{\frac{3}{2}}} = 0$$

In consequence, we have the equations

$$\int_{0}^{\frac{\pi}{2}} \frac{(1-c^{2}) dT}{[1-c^{2} \sin^{2} T]^{\frac{3}{2}}} = E^{1} (c)$$

$$\int_{0}^{\frac{\pi}{2}} \frac{\sin^{2} T dT}{[1-c^{2} \sin^{2} T]^{\frac{3}{2}}} = \frac{1}{c^{2}} \left[\frac{1}{b^{2}} E^{1} (c) - F^{1} (c) \right]$$

$$\int_{0}^{\frac{\pi}{2}} \frac{\cos^{2} T dT}{[1-c^{2} \sin^{2} T]^{\frac{3}{2}}} = \frac{1}{c^{2}} \left[F^{1} (c) - E^{1} (c) \right]$$

Legendre, moreover, has put

$$F^{1}(c) = \frac{\pi}{2} K$$
 $E^{1}(c) = \frac{\pi}{2} K L$

Hence,

$$R_{0}, S_{0}, \text{ or } W_{0} = \frac{K}{c^{2}(G+G'')^{\frac{3}{2}}} \left[(\Gamma' + 2\Gamma'' + f) (\mathbf{I} - \mathbf{L}) + (2\Gamma' + \Gamma'' + f) \left(\frac{\mathbf{L}}{b^{2}} - \mathbf{I} \right) \right]$$

$$= \frac{KL}{b^{2}(G+G'')^{\frac{3}{2}}} f + \frac{K}{(G+G'')^{\frac{3}{2}}} \left[\frac{\mathbf{L}}{b^{2}} + \frac{\mathbf{L} - b^{2}}{b^{2}c^{2}} \right] \Gamma' + \frac{K}{(G+G'')^{\frac{3}{2}}} \left[2\frac{\mathbf{L}}{b^{2}} - \frac{\mathbf{L} - b^{2}}{b^{2}c^{2}} \right] \Gamma''$$

We will now put

$$\mathbf{X} = \frac{\mathbf{KL}}{b^2} \qquad \qquad \mathbf{E} = \frac{\mathbf{L} - b^2}{c^2 \mathbf{L}}$$

In consequence, the general expression for R₀, S₀, or W₀ will take the form

$$\frac{\mathfrak{Z}}{(\mathbf{G}+\mathbf{G}'')^{\frac{2}{3}}} \left\lceil f + (\mathbf{I}+\mathbf{Z}) \ \Gamma' + (\mathbf{2}-\mathbf{Z}) \ \Gamma'' \right\rceil$$

If we put

$$N = \frac{ar^2 \mathcal{X}}{(G + G'')^{\frac{3}{2}}} \qquad N' = \frac{N (1 + \mathcal{X})}{b^2 c^2 (G + G'')^{\frac{3}{2}}} \qquad N'' = \frac{N (2 - \mathcal{X})}{c^2 (G + G'')^2}$$

and substitute for Γ' and Γ'' their values, this expression becomes

$$(N' - N'') \frac{F}{ar^2} + (N'G' + N''G'') \frac{J}{ar^2} + (N + N'G'^2 - N''G''^2) \frac{f}{ar^2}$$

This can be rendered more suitable for computation by putting

$$P = N' - N'' = \frac{N \left[-2b^2 + t + (t + b^2) \mathcal{L} \right]}{b^2 c^2 (G + G'')^2}$$

$$Q = N' (G' + G'') = \frac{N (t + \mathcal{L})}{b^2 (G + G'')}$$

$$V = Q - PG''$$

Then the expression takes the form

$$P\frac{F}{ar^2} + V\frac{J}{ar^2} + (N + QG' - VG'')\frac{f}{ar^2}$$

If we call $\frac{F}{ar^2}$, $\frac{J}{ar^2}$, and $\frac{f}{ar^2}$ severally in the cases of R_0 , S_0 , and W_0 by F_1 , J_1 , f_1 , F_2 , J_2 , f_2 , F_3 , J_3 , f_3 , remembering that $F_1 = 0$, $f_1 = -1$, $f_2 = 0$, and $f_3 = 0$, we shall have

$$R_0 = -(\dot{N} + QG' - VG'') + VJ_1$$

 $S_0 = PF_2 + VJ_2$
 $W_0 = PF_3 + VJ_3$

It now only remains to show how the elliptic integrals K and L may be computed. If we adopt a new variable, T⁰, such that

$$\sin (2T - T^0) = c^0 \sin T^0$$

where $c^0 = \frac{1-b}{1+b}$, we shall have the following equations.

$$\cos (2T - T^{0}) = \checkmark (1 - c^{0^{2}} \sin^{2} T^{0}) = \triangle$$

$$\cos 2T = \triangle \cos T^{0} - c^{0} \sin^{2} T^{0}$$

$$\sin 2T = \triangle \sin T^{0} + c^{0} \sin T^{0} \cos T^{0}$$

$$= \sin T^{0} (c^{0} \cos T^{0} + \triangle)$$

$$2dT = \frac{dT^{0}}{\triangle} (c^{0} \cos T^{0} + \triangle)$$

$$\checkmark (1 - c^{2} \sin^{2} T) = \frac{c^{0} \cos T^{0} + \triangle}{1 + c^{0}}$$

$$\frac{dT}{\checkmark (1 - c^{2} \sin^{2} T)} = \frac{1 + c^{0}}{2} \frac{dT^{0}}{\triangle}$$

which constitute the well-known transformation of Landen. It is plain, from the values of $\sin(2T - T^0)$ and $\cos(2T - T^0)$ that, when T passes from the value o to

the value $\frac{\pi}{2}$, To passes from 0 to π . Hence,

$$\int_0^{\frac{\pi}{2}} \frac{d\mathbf{T}}{\sqrt{(1-c^2\sin^2\mathbf{T})}} = (1+c^0) \int_0^{\frac{\pi}{2}} \frac{d\mathbf{T}^0}{\sqrt{(1-c^{02}\sin^2\mathbf{T}^0)}}$$

or

$$F^{1}(c) = (1 + c^{0}) F^{1}(c^{0})$$

If we take c^{00} the same function of c^0 that c^0 is of c, and, again, in like manner, derive c^{000} , and so on, the quantities c, c^0 , c^{00} , &c., diminish, and, as $F^1(0) = \frac{\pi}{2}$, we shall have

$$F^{1}(c) = \frac{\pi}{2} (I + c^{0}) (I + c^{00}) (I + c^{000}) ...$$

If the moduli complementary to c^0 , c^{00} , &c., are denoted by b^0 , b^{00} , &c., we shall have $b^0 = \sqrt{1-c^{02}}$ and $b = \frac{1-c^0}{1+c^0}$. Consequently,

$$(\mathbf{1}+c^0) = \frac{b^0}{\sqrt{h}}$$

Hence,

$$K = \sqrt{\frac{\overline{b^0} \, \overline{b^{00}} \, \overline{b^{000}} \dots}{b}}$$

From the equations

$$\frac{d\mathbf{T}}{\sqrt{(1-c^2\sin^2\mathbf{T})}} = \frac{\mathbf{I}+c^0}{2} \frac{d\mathbf{T}^0}{\Delta} \qquad \qquad \sin^2\mathbf{T} = \frac{\mathbf{I}}{2} \left(\mathbf{I}+c^0\sin^2\mathbf{T}^0 - \Delta\cos\mathbf{T}^0\right)$$

we obtain

$$\int_{0}^{\frac{\pi}{2}} \frac{A + B \sin^{2} T}{\sqrt{(1 - c^{2} \sin^{2} T)}} dT = (1 + c^{0}) \int_{0}^{\frac{\pi}{2}} \frac{A + \frac{B}{2} + B \frac{c^{0}}{2} \sin^{2} T^{0}}{\Delta} dT^{0}$$

If this process of transformation is continued as in the case of the former integral we find that

$$\int_{0}^{\frac{\pi}{2}} \frac{A + B \sin^{2} T}{\sqrt{(1 - c^{2} \sin^{2} T)}} dT = \frac{\pi}{2} K \left[A + \frac{B}{2} \left(1 + \frac{c^{0}}{2} + \frac{c^{0} c^{00}}{4} + \frac{c^{0} c^{00} c^{000}}{8} + \dots \right) \right]$$

In the case of $E^{1}(c)$ we have A = 1 and $B = -c^{2}$; hence,

$$L = I - \frac{c^2}{2} - \frac{c^2 c^0}{4} - \frac{c^2 c^0 c^{00}}{8} - \dots$$

As we have

$$1 - \frac{c^2}{2} - \frac{c^2 c^0}{4} = \frac{c^2}{4c^0} = \frac{b}{b^{0^2}}$$

and as we may, for our purpose, cut off the series at the term which contains c^{000} , and with sufficient approximation put

$$1 + \frac{1}{2}c^{000} = \sqrt{1 + c^{000}} = \sqrt{\frac{2\sqrt{c^{000}}}{c^{00}}} = \frac{\sqrt{b^{000}}}{\sqrt{b^{00}}}$$

we may put

$${
m L} \equiv rac{b}{ar{b}^{0\,2}} \left[{
m I} - rac{{
m I}}{2} \, c^{0^2} \, c^{00} \, \sqrt[4]{ar{b}^{000}}
ight]$$

In like manner

$$\frac{\mathbf{L} - b^{2}}{c^{2}} = \frac{1}{2} \left[\mathbf{I} - \frac{c^{0}}{2} - \frac{c^{0}}{4} \frac{c^{00}}{\sqrt{b^{00}}} \right]$$

$$\mathbf{E} = \sqrt{\frac{\overline{b^{00}} \, \overline{b^{000}}}{b^{3} \, \overline{b^{0}}^{3}}} \left[\mathbf{I} - \frac{1}{2} \, c^{0^{2}} \, c^{00} \frac{\sqrt{b^{000}}}{\sqrt{b^{00}}} \right]$$

$$\frac{(\mathbf{I} + b^{2}) \, \mathbf{E} - 2 \, b^{2} + \mathbf{I}}{b^{2} \, c^{2}} = \mathbf{E}' = \frac{2 - c^{2} - \frac{(\mathbf{I} - c^{2} + c^{4})}{8} \, b^{0^{2}} \left(\mathbf{I} + \frac{1}{2} \, c^{00} \, \frac{\sqrt{b^{000}}}{\sqrt{4} \sqrt{b^{00}}} \right)}{\frac{b^{3}}{b^{0^{2}}} \left[\mathbf{I} - \frac{1}{2} \, c^{0^{2}} \, c^{00} \, \frac{\sqrt{b^{000}}}{\sqrt{b^{00}}} \right]}$$

$$\frac{\mathbf{I} + \mathbf{E}}{b^{2}} = \mathbf{E}' = \frac{\frac{3}{2} - \frac{1}{2} \, c^{2} - \frac{\mathbf{I} + c^{2}}{2} \left[\frac{c^{0}}{2} + \frac{c^{0}}{4} \frac{c^{0}}{\sqrt{b^{00}}} \right]}{\frac{b^{3}}{b^{0^{2}}} \left[\mathbf{I} - \frac{1}{2} \, c^{0^{2}} \, c^{00} \, \frac{\sqrt{b^{000}}}{\sqrt{b^{00}}} \right]}$$

The common logarithms of the last three functions are tabulated at the end of this memoir. In order to make the data of Legendre's Tables in the second volume of his Théorie des Fonctions Elliptiques available, c has been put $\equiv \sin \theta$, and θ adopted as the argument. The quantities are given to eight places of decimals, having been computed with ten. They are tabulated at intervals of a tenth of a degree, and are given from $\theta \equiv 0$ up to $\theta \equiv 50^{\circ}$. Beyond the latter limit they will scarcely be needed and the interpolation of the tables becomes difficult. Should values, beyond the limit of the table, be wanted, it will be easier to compute them directly from the formulæ than to derive them by interpolation from values tabulated at intervals of 0° . I in the value of θ .

Recapitulation of the formulæ needed for the application of this method.

For the benefit of those who wish to make a numerical application of this method, I have here gathered together and arranged, in proper order, all the formulæ necessary to be used. For the signification of the symbols, the preceding discussion must be consulted.

Compute the constants I, Π , Π' , k, K, k', and C, which are functions of the elements of the two orbits, by means of the equations

$$\sin I \cos (\Pi - \omega) \equiv -\sin i \cos i' + \cos i \sin i' \cos (\Omega' - \Omega)$$

$$\sin I \sin (\Pi - \omega) \equiv -\sin i' \sin (\Omega' - \Omega)$$

$$\sin I \cos (\Pi' - \omega') \equiv \cos i \sin i' - \sin i \cos i' \cos (\Omega' - \Omega)$$

$$\sin I \sin (\Pi' - \omega') \equiv -\sin i \sin i \sin (\Omega' - \Omega)$$

$$k \cos (K - \Pi) \equiv \cos \Pi'$$

$$k \sin (K - \Pi) \equiv -\cos I \sin \Pi'$$

$$k' \cos (K' - \Pi) \equiv -\sin \Pi'$$

$$C \equiv a'^2 e'^2$$

The circumference, with reference to the variable E, will now be divided into a certain number of equal parts, which number ought to be a multiple of 4, and should be large or small as the perturbations are more or less irregular through the variation of the distance of the two planets. For each of these values of E, the values of the varying quantities in the left members of the following equations must be calculated. Here a useful check against large errors may be had by adding the first, third, fifth, &c., numerical values of any one of these quantities, and again the second, fourth, sixth, &c. The difference of the two sums should be very small, except in case of certain angles, where one sum may exceed the other by nearly 180°. The same test may be applied to the logarithms of a quantity, provided it does not change sign and does not approach zero very closely.

$$r \cos v \equiv a (\cos E - e)$$

$$r \sin v \equiv a \cos \varphi \sin E$$

$$A \equiv r^2 + 2ka'e'r \cos (v + K) + a'^2$$

$$B \cos \varepsilon \equiv ka'r \cos (v + K) + a'^2 e'$$

$$B \sin \varepsilon \equiv k'a' \cos \varphi'. r \sin (v + K')$$

$$g \equiv B^2 C \sin^2 \varepsilon$$

$$h = \frac{1}{2} \left[A - C + \sqrt{(A+C)^2 - 4B^2} \right]$$

$$l \equiv \frac{1}{2} \left[A - C - \sqrt{(A+C)^2 - 4B^2} \right]$$

Find G, G', and G" by trial from the equations

$$G = h - \frac{g}{G(G - l)}$$

$$G' = l + \frac{g}{G'(h - G')}$$

$$G'' = \frac{g}{(h + G'')(l + G'')}$$

Approximate values are

$$G = h - \frac{g}{h(h-l)}$$

$$G' = l + \frac{g}{l(h-l)}$$

$$G'' = \frac{g}{\left(h + \frac{g}{hl}\right)\left(l + \frac{g}{hl}\right)}$$

$$\sin^2 \theta = \frac{G' + G''}{G + G''}$$

From the tables at the end of this memoir, with the argument θ , take out the values of $\log \mathfrak{U}$, $\log \mathfrak{U}'$, and $\log \mathfrak{U}$.

$$N = \frac{ar^{2}}{(G + G'')^{\frac{3}{2}}}$$

$$P = \frac{N \mathcal{L}'}{(G + G'')^{2}}$$

$$Q = \frac{N \mathcal{L}'}{G + G''}$$

$$V = Q - PG''$$

$$J_{1} = a'^{2} \cos^{2} \varphi' \left[1 - \sin^{2} I \sin^{2} (v + II)\right] + G''$$

$$J_{2} = ka'e'r \sin (v + K) - \frac{1}{2} a'^{2} \cos^{2} \varphi' \sin^{2} I \sin 2 (v + II)$$

$$J_{3} = \frac{a'^{2}}{a} \cos^{2} \varphi' \sin I \cos I. \ r \sin (v + II) - \frac{a'}{a} e' \sin I \sin II. \ r^{2}$$

$$F_{2} = -a'^{2} \sin \varphi' \cos \varphi' \cos I. \ B \sin \varepsilon$$

$$F_{3} = -\frac{a'^{2}}{a} \sin \varphi' \cos \varphi' \sin I. \ r \cos (v + II). \ B \sin \varepsilon$$

$$R_{0} = -N - QG' + VJ_{1}$$

$$S_{0} = PF_{2} + VJ_{2}$$

$$W_{0} = PF_{3} + VJ_{3}$$

The secular variations of the elements will be given by the following equations:

$$\begin{bmatrix} \frac{de}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \cos \varphi. \, M_{E} \begin{bmatrix} \sin v. \, R_{0} + (\cos v + \cos E) \, S_{0} \end{bmatrix}$$

$$e \begin{bmatrix} \frac{d\chi}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \cos \varphi. \, M_{E} \begin{bmatrix} -\cos v. \, R_{0} + \left(\frac{r}{a \cos^{2} \varphi} + 1\right) \sin v. \, S_{0} \end{bmatrix}$$

$$\begin{bmatrix} \frac{di}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \sec \varphi. \, M_{E} \begin{bmatrix} \cos u. \, W_{0} \end{bmatrix}$$

$$\sin i \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \sec \varphi. \, M_{E} \begin{bmatrix} \sin u. \, W_{0} \end{bmatrix}$$

$$\begin{bmatrix} \frac{d\pi}{dt} \end{bmatrix}_{00} = \begin{bmatrix} \frac{d\chi}{dt} \end{bmatrix}_{00} + 2 \sin^{2} \frac{i}{2} \cdot \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00}$$

$$\begin{bmatrix} \frac{dL}{dt} \end{bmatrix}_{00} = \frac{m'n}{1+m} \, M_{E} \begin{bmatrix} -2\frac{r}{a} \, R_{0} \end{bmatrix} + 2 \sin^{2} \frac{\varphi}{2} \cdot \begin{bmatrix} \frac{d\chi}{dt} \end{bmatrix}_{00} + 2 \sin^{2} \frac{i}{2} \cdot \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00}$$

EXAMPLE.

Computation of the Secular Perturbations of Mercury produced by the Action of Venus.

The elements of the two planets, adopted for the epoch 1850.0, are

Mercury.
$$n = 5381016''.26$$
 $n' = 2106641''.357$ $e = 0.20560476$ $e' = 0.00684311$ $\pi = 75^{\circ}$ 7' 13''.62 $\pi' = 129^{\circ}$ 27' 42''.83 $i = 7^{\circ}$ 0' 7''.71 $i' = 3^{\circ}$ 23' 35''.01 $\Omega = 46^{\circ}$ 33' 8''.63 $\Omega' = 75^{\circ}$ 19' 53''.08 $\log a = 9.5878217$ $\log a' = 9.8593378$ $m = \frac{1}{5000000}$

From these are deduced

$$I = 4^{\circ} 20' 42''.98$$
 $K = 305^{\circ} 43' 2''.46$ $\log k' = 9.9999176$ $\Pi = 230^{\circ} 39' 31''.39$ $K' = 305^{\circ} 47' 57''.54$ $\log C = 5.3891826$ $\Pi' = 284^{\circ} 54' 1''.18$ $\log k = 9.9988328$ $C = 0.00002450$

The circumference is now divided into twelve parts with respect to E, the eccentric anomaly of Mercury. The values of the various quantities employed in the computation, computed for each of the points of division, are tabulated below. The result of the application of the test, mentioned above, is given at the foot of the column, opposite

to the symbols S and S', whenever it is supposed to be useful. The numbers given are affected with asterisks when the additions have been made on the numbers which correspond to the logarithms in the column of values.

Dividing the numbers at the foot of the last five columns by 12, we have the average values of the several functions written at the top. And, leaving the mass of Venus indefinite, we have

$$\begin{bmatrix} \frac{de}{dt} \end{bmatrix}_{00}^{\text{log. coeff.}} + 11321''.28 \ m' & 4.0538954 \\ \begin{bmatrix} \frac{dX}{dt} \end{bmatrix}_{00}^{\text{log. coeff.}} + 1133122'' & m' & 6.0542766 \\ \begin{bmatrix} \frac{di}{dt} \end{bmatrix}_{00}^{\text{log. coeff.}} + 1133122'' & m' & 6.0542766 \\ \begin{bmatrix} \frac{di}{dt} \end{bmatrix}_{00}^{\text{log. coeff.}} + 14.7813907 \\ \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00}^{\text{log. coeff.}} + 1127210'' & m' & n 5.8990565 \\ \begin{bmatrix} \frac{d\Omega}{dt} \end{bmatrix}_{00}^{\text{log. coeff.}} + 1127210'' & m' & 6.0520049 \\ \begin{bmatrix} \frac{dL}{dt} \end{bmatrix}_{00}^{\text{log. coeff.}} + 1326648''.7 \ m' & n 6.1227559 \end{bmatrix}$$

The eccentricity e is supposed to be expressed in seconds of arc; if the variation in parts of the radius is wanted, the result given above must be multiplied by the factor whose logarithm is 94 6855749. It is scarcely necessary to add that the unit of time is the Julian year, and that m' must be expressed in parts of the sun's mass.

If we adopt Leverrier's value of m', viz, $m' = \frac{1}{401847}$, we have the values of the secular variations given below. Alongside, for the sake of comparison, I put Leverrier's values, deduced from the series expanded in powers of the eccentricities and mutual inclination of the plane of the orbits. (Annales de l'Observatoire de Paris. Mémoires. Tome V, pp. 6-7-21.)

$$\begin{bmatrix} \frac{de}{dt} \end{bmatrix}_{00} = + \text{ o''.0281731} + \text{ o''.02823} \\ + \text{ o''.02823} + \text{ o''.02823} \\ \frac{d\pi}{dt} \end{bmatrix}_{00} = + \text{ 2''.805073} + \text{ 2''.8064} \\ \frac{di}{dt} \end{bmatrix}_{00} = - \text{ o''.1504284} - \text{ o''.15044} \\ \frac{d\Omega}{dt} \end{bmatrix}_{00} = - \text{ 1''.972403} - \text{ 1''.9702} \\ \frac{dL}{dt} \end{bmatrix}_{00} = - \text{ 3''.301377} - \text{ 3''.3282}$$

Table of the Values of Three Elliptic Integrals employed in this Memoir.

ADDENDUM.

Since the preceding portion of this memoir was in type it has occurred to me that some of the processes might be modified with advantage.

First, the roots of the equation

$$x \left[(x - A) (x + C) + B^2 \right] + B^2 C \sin^2 \varepsilon = 0$$

can be obtained by the well-known trigonometric method. If we put

$$p = \frac{I}{3} (A - C)$$

$$q^2 = p^2 - \frac{I}{3} (B^2 - AC)$$

$$r = \frac{I}{2} p (p^2 - 3 q^2) + \frac{I}{2} B^2 C \sin^2 \epsilon$$

$$\sin \theta = \tau = \frac{r}{q^3}$$

and if θ is taken between the limits $\pm 90^{\circ}$, the three quantities G, G', and G" are given by the equations

G = 2 q sin
$$\left(60^{\circ} - \frac{\theta}{3}\right) + p$$

G' = 2 q sin $\frac{\theta}{3} + p$
G" = 2 q sin $\left(60^{\circ} + \frac{\theta}{3}\right) - p$

From these equations we derive the following:

G + G" =
$$2\sqrt{3}$$
 q cos $\frac{\theta}{3}$
G' + G" = $2\sqrt{3}$ q cos $\left(60^{\circ} - \frac{\theta}{3}\right)$
G - G' = $2\sqrt{3}$ q cos $\left(60^{\circ} + \frac{\theta}{3}\right)$

If these values are substituted in the equations

$$\Gamma' = \frac{F + JG' + fG'^2}{(G' + G'')(G - G')} \qquad \Gamma'' = \frac{-F + JG'' - fG''^2}{(G + G'')(G' + G'')}$$

we obtain

$$\Gamma' = \frac{\Gamma + Jp + f(p^2 + 2q^2) + 2(J + 2fp)q\sin\frac{\theta}{3} - 2fq^2\cos\frac{2}{3}\theta}{12q^2\cos\left(60^\circ - \frac{\theta}{3}\right)\cos\left(60^\circ + \frac{\theta}{3}\right)}$$

$$\Gamma'' = \frac{-\left[\Gamma + Jp + f(p^2 + 2q^2)\right] + 2(J + 2fp)q\sin\left(60^\circ + \frac{\theta}{3}\right) + 2fq^2\cos\left(120^\circ + \frac{2}{3}\theta\right)}{12q^2\cos\frac{\theta}{3}\cos\left(60^\circ - \frac{\theta}{2}\right)}$$

Or, since we have

$$\Gamma' = \frac{\left[F + J p + f(p^2 + q^2)\right] \cos \frac{\theta}{3} + (J + 2 f p) q \sin \frac{2}{3} \theta}{3 q^2 \cos \theta} - \frac{1}{3} f$$

$$\Gamma'' = \frac{-\left[F + J p + f(p^2 + q^2)\right] \cos \left(60^\circ + \frac{\theta}{3}\right) + (J + 2 f p) q \sin \left(120^\circ + \frac{2}{3}\theta\right)}{3 q^2 \cos \theta} - \frac{1}{3} f$$

From these equations we derive

$$\Gamma' + 2 \Gamma'' + f = \frac{[F + J p + f(p^2 + q^2)] \sin \frac{\theta}{3} + (J + 2 f p) q \cos \frac{2}{3} \theta}{\sqrt{3} q^2 \cos \theta}$$

$${}_{2} I^{\mathsf{v}} + I^{\mathsf{v}'} + f = \frac{[F + Jp + f(p^{2} + q^{2})] \sin\left(60^{\circ} + \frac{\theta}{3}\right) + (J + 2fp) q \cos\left(60^{\circ} - \frac{2}{3}\theta\right)}{\sqrt{3} q^{2} \cos\theta}$$

The values of R₀, S₀, and W₀ are given by the integral

$$\frac{2}{\pi} \int_{0}^{\frac{\pi}{2}} \frac{\left[\Gamma' + 2 \Gamma'' + f\right] \cos^{2} T + \left[2 \Gamma' + \Gamma'' + f\right] \sin^{2} T}{\left(2 \sqrt{3} q\right)^{\frac{3}{2}} \left[\cos \frac{\theta}{3} \cos^{2} T + \cos \left(60^{\circ} + \frac{\theta}{3}\right) \sin^{2} T\right]^{\frac{3}{2}}} dT$$

provided we attribute to F, J, and f the values they severally have in each case. Let us put

$$m^{2} = \cos \frac{\theta}{3}$$

$$n^{2} = \cos \left(60^{\circ} + \frac{\theta}{3}\right)$$

$$a = \frac{F + J p + f(p^{2} + q^{2})}{6 \sqrt[4]{12} q^{\frac{\pi}{2}}}$$

$$b = \frac{J + 2 f p}{6 \sqrt[4]{12} q^{\frac{\pi}{2}}}$$

Then the integral, just given, takes the form

$$\frac{2}{\pi} \int_{0}^{\frac{\pi}{2}} \left[a \sin \frac{\theta}{3} + b \cos \frac{2}{3} \theta \right] \cos^{2}T + \left[a \sin \left(60^{\circ} + \frac{\theta}{3} \right) + b \cos \left(60^{\circ} - \frac{2}{3} \theta \right) \right] \sin^{2}T dT$$

$$\cos \theta \left[m^{2} \cos^{2}T + n^{2} \sin^{2}T \right] \frac{\pi}{2}$$

In the second place Gauss's processes for approximating to the values of the integrals may be employed instead of those of Legendre. The equation between definite integrals

$$\int_0^{\frac{\pi}{2}} \sqrt{(1-c^2\sin^2 T)} = (1+c^0) \int_0^{\frac{\pi}{2}} \frac{dT}{\sqrt{(1-c^{02}\sin^2 T)}}$$

may be easily transformed into

$$\int_{0}^{\frac{\pi}{2}} \frac{dT}{[m^{2}\cos^{2}T + n^{2}\sin^{2}T]\frac{1}{2}} = \int_{0}^{\frac{\pi}{2}} \frac{dT}{[m'^{2}\cos^{2}T + n'^{2}\sin^{2}T]\frac{1}{2}}$$

where

$$m' \equiv \frac{1}{2} (m + n)$$
 $n' \equiv \sqrt{mn}$

when we remember that

$$c^2 = \frac{m^2 - n^2}{m^2}$$
 $c^0 = \frac{m - n}{m + n}$

If this mode of transformation is continued, and we compute

$$m'' = \frac{1}{2} (m' + n')$$
 $n'' = \sqrt{m' n'}$
 $m''' = \frac{1}{2} (m'' + n'')$ $n''' = \sqrt{m'' n''}$

the series of quantities, m, m', m", etc., and n, n', n", etc., converge very rapidly toward a common limit μ , which Gauss has called the *arithmetico-geometrical mean* between m and n. Then,

$$\frac{2}{\pi} \int_{0}^{\frac{\pi}{2}} \frac{d\mathbf{T}}{[\mathbf{m}^{2} \cos^{2} \mathbf{T} + \mathbf{n}^{2} \sin^{2} \mathbf{T}]^{\frac{1}{2}}} = \frac{1}{\mu}$$

The equation

$$\frac{2}{\pi} \int_{0}^{\frac{\pi}{2}} \frac{A + B \sin^{2} T}{\sqrt{(I - c^{2} \sin^{2} T)}} dT = K \left[A + \frac{B}{2} \left(I + \frac{c^{0}}{2} + \frac{c^{0} c^{00}}{4} + \frac{c^{0} c^{00}}{8} + \ldots \right) \right]$$

on putting

$$A = -\frac{I}{m} \qquad B = \frac{2}{m}$$

is readily transformed into

$$\frac{2}{\pi} \int_{0}^{\frac{\pi}{2}} \frac{\sin^{2} T - \cos^{2} T}{[m^{2} \cos^{2} T + n^{2} \sin^{2} T]^{\frac{1}{2}}} dT = \frac{1}{\mu} \left[\frac{m-n}{2(m+n)} + \frac{m-n}{2(m+n)} \frac{m'-n'}{2(m'+n')} + \dots \right]$$

The series within the brackets may be denoted by ν . It can be transformed as follows:

$$\nu = \frac{m^2 - n^2}{8 m'^2} + \frac{m^2 - n^2}{8 m'^2} \frac{m'^2 - n'^2}{8 m''^2} + \frac{m^2 - n^2}{8 m''^2} \frac{m''^2 - n''^2}{8 m''^2} \frac{m''^2 - n''^2}{8 m''^2} + \dots$$

$$= \frac{m^2 - n^2}{8 m'^2} + \frac{m^2 - n^2}{8 m'^2} \frac{(m^2 - n^2)^2}{128 m''^2 m''^2} + \frac{m^2 - n^2}{8 m'^2} \frac{(m^2 - n^2)^2}{128 m''^2 m''^2} \frac{(m'^2 - n'^2)^2}{128 m''^2 m''^2} + \dots$$

As this mode of transformation may be continued indefinitely, it is plain, that if we compute the series of quantities

$$\lambda = \frac{1}{4} \checkmark (m^2 - n^2)$$
 $\lambda' = \frac{\lambda^2}{m'}$ $\lambda'' = \frac{\lambda''^2}{m''}$ $\lambda''' = \frac{\lambda''^2}{m'''}$

we shall have

$$\nu = \frac{2 \lambda'^2 + 4 \lambda''^2 + 8 \lambda'''^2 + \dots}{\lambda^2}$$

The equation

$$\int_{0}^{\frac{\pi}{2}} \frac{1-2}{1-c^{2} \sin^{2} T} \frac{1+c^{2} \sin^{4} T}{1-c^{2} \sin^{2} T} \frac{1}{2} dT = 0$$

is readily transformed into

$$\int_{0}^{\frac{\pi}{2}} \frac{\mathrm{m}^{2} \cos^{4} \mathrm{T} - \mathrm{n}^{2} \sin^{4} \mathrm{T}}{\left[\mathrm{m}^{2} \cos^{2} \mathrm{T} + \mathrm{n}^{2} \sin^{2} \mathrm{T}\right]^{\frac{3}{2}}} d\mathrm{T} = 0$$

Whence we conclude that

$$\frac{\pi}{2} \int_{0}^{\frac{\pi}{2}} \frac{\cos^{2} T}{\left[m^{2} \cos^{2} T + n^{2} \sin^{2} T\right]^{\frac{3}{2}}} dT = \frac{1 + \nu}{2 m^{2} \mu}$$

$$\frac{\pi}{2} \int_{0}^{\frac{\pi}{2}} \frac{\sin^{2} T}{\left[m^{2} \cos^{2} T + n^{2} \sin^{2} T\right]^{\frac{3}{2}}} dT = \frac{1 - \nu}{2 n^{2} \mu}$$

Substituting these values in the general integral expression for R⁰, S⁰, and W⁰, we get

$$R^{0}, S^{0}, \text{ or } W^{0} = \frac{a}{\cos \theta} \left[\frac{1 + \nu}{2 \mu} \tan \frac{\theta}{3} + \frac{1 - \nu}{2 \mu} \tan \left(60^{\circ} + \frac{\theta}{3} \right) \right]$$

$$+ \frac{b}{\cos \theta} \left[\frac{1 + \nu}{2 \mu} \frac{\cos \frac{2\theta}{3}}{\cos \frac{\theta}{3}} + \frac{1 - \nu}{2 \mu} \frac{\cos \left(60^{\circ} - \frac{2\theta}{3} \right)}{\cos \left(60^{\circ} + \frac{\theta}{3} \right)} \right]$$

This expression presents the inconvenience of taking the indeterminate form o when the modulus c vanishes and when $\theta = -90^{\circ}$. This is avoided by putting

$$\nu' = \frac{\sqrt{3}}{64} \frac{\nu}{\lambda^2}$$

where we recall that

$$\lambda^2 = \frac{1}{16} \cos \left(60^{\circ} - \frac{\theta}{3} \right)$$

and transforming the expression into the shape

$$a \frac{\sin\left(60^{\circ} - \frac{\theta}{3}\right) - \nu'}{4 \mu \cos^{2}\frac{\theta}{3}\cos^{2}\left(60^{\circ} + \frac{\theta}{3}\right)} + b \frac{\frac{1}{2} + \cos\frac{\theta}{3}\cos\left(60^{\circ} + \frac{\theta}{3}\right) - \nu'\sin\theta}{4 \mu \cos^{2}\frac{\theta}{3}\cos^{2}\left(60^{\circ} + \frac{\theta}{3}\right)}$$

This may be written, if we choose, in the briefer manner

$$a \frac{\sin \left(60^{\circ} - \frac{\theta}{3}\right) - \nu'}{4 m^{4} n^{4} \mu} + b \frac{\frac{1}{2} + m^{2} n^{2} - \nu' \sin \theta}{4 m^{4} n^{4} \mu}$$

The factors of a and b in this expression are functions of τ , and their common logarithms might be tabulated with τ as the argument.

We will now put

$$\chi(\tau) = -\frac{\sin\left(60^{\circ} - \frac{\theta}{3}\right) - \nu'}{\frac{24^{\circ}}{3}\sqrt{\frac{12}{12}} \frac{m^{4}}{m^{4}} \frac{n^{4}}{\mu}} \qquad \psi(\tau) = \frac{\frac{1}{2} + m^{2}}{\frac{24}{3}\sqrt{\frac{12}{12}} \frac{m^{4}}{m^{4}} \frac{n^{4}}{\mu}}$$

as also

$$V = \frac{p}{q} \chi (\tau) + \psi (\tau)$$

Then, if

$$F_{1} = \frac{B^{2} - AC}{3 a^{\prime 2} \cos^{2} \varphi^{\prime}. q}$$

$$F_{2} = -\tan \varphi^{\prime} \cos I. \quad \frac{B \sin \varepsilon}{q}$$

$$F_{3} = -\tan \varphi^{\prime} \sin I. \frac{r}{a} \cos (v + \Pi). \quad \frac{B \sin \varepsilon}{q}$$

$$J_{1} = I - \sin^{2} I \sin^{2} (v + \Pi) - \frac{2 p}{a^{\prime 2} \cos^{2} \varphi^{\prime}}$$

$$J_{2} = k\alpha \frac{\tan \varphi^{\prime}}{\cos \varphi^{\prime}} \frac{r}{a} \sin (v + K) - \frac{1}{2} \sin^{2} I \sin 2 (v + \Pi)$$

$$J_{3} = \sin I \cos I. \frac{r}{a} \sin (v + \Pi) - \alpha \frac{\tan \varphi^{\prime}}{\cos \varphi^{\prime}} \sin I \sin \Pi. \frac{r^{2}}{a^{2}}$$

where α denotes $\frac{a}{a'}$, we shall have the following equations

$$\frac{a}{r} R_0 = a^2 a'^2 \cos^2 \varphi'. \ r \ q^{-\frac{5}{2}} \left[F_1 \chi (\tau) + J_1 V \right]$$

$$\frac{a}{r} S_0 = a^2 a'^2 \cos^2 \varphi'. \ r \ q^{-\frac{5}{2}} \left[F_2 \chi (\tau) + J_2 V \right]$$

$$\frac{a}{r} W_0 = a^2 a'^2 \cos^2 \varphi'. \ r \ q^{-\frac{5}{2}} \left[F_3 \chi (\tau) + J_3 V \right]$$

Why we multiply the members of these equations by $\frac{a}{r}$ will presently appear.

A third modification, which seems advantageous, is to apply the process of mechanical quadratures to the quantities $\frac{a}{r} R_0$, $\frac{a}{r} S_0$, and $\frac{a}{r} W_0$, instead of applying it to the variations of the elements. If we multiply the factors of R_0 , S_0 , and W_0 , in the expressions for the variations of the elements, by the factor $\frac{r}{a}$, they become integral functions of sin E and cos E. And thus we have

$$\begin{bmatrix} \frac{d}{d} \frac{\varphi}{t} \end{bmatrix}_{00} = \frac{m'}{1+m} M_{E} \begin{bmatrix} \cos \varphi \sin E \cdot \frac{a}{r} R_{0} + \left(-\frac{3}{2}e + 2 \cos E - \frac{e}{2} \cos 2 E \right) \frac{a}{r} S_{0} \end{bmatrix}$$

$$e \begin{bmatrix} \frac{d}{d} \chi \\ \frac{d}{t} \end{bmatrix}_{00} = \frac{m'}{1+m} M_{E} \begin{bmatrix} -\cos \varphi (\cos E - e) \frac{a}{r} R_{0} + \left((2 - e^{2}) \sin E - \frac{e}{2} \sin 2 E \right) \frac{a}{r} S_{0} \end{bmatrix}$$

$$\begin{bmatrix} \frac{d}{d} \frac{i}{t} \end{bmatrix}_{00} = \frac{m'}{1+m} M_{E} \begin{bmatrix} (-\tan \varphi \cos \omega + \sec \varphi \cos \omega \cos E - \sin \omega \sin E) \frac{a}{r} W_{0} \end{bmatrix}$$

$$\sin i \begin{bmatrix} \frac{d}{\omega} \frac{\Omega}{dt} \end{bmatrix}_{00} = \frac{m'}{1+m} M_{E} \begin{bmatrix} (-\tan \varphi \sin \omega + \sec \varphi \sin \omega \cos E + \cos \omega \sin E) \frac{a}{r} W_{0} \end{bmatrix}$$

$$\frac{m'}{1+m} M_{E} \begin{bmatrix} -2\frac{r}{a} R_{0} \end{bmatrix} = \frac{m'}{1+m} M_{E} \begin{bmatrix} (-(2+e^{2}) + 4e \cos E - e^{2} \cos 2 E \right) \frac{a}{r} R_{0} \end{bmatrix}$$

The quantities $\frac{a}{r}$ R₀, $\frac{a}{r}$ S₀, and $\frac{a}{r}$ W₀, by the application of mechanical quadratures, must now be developed in periodic series with the argument E, so that we have

$$\begin{split} &\frac{a}{r} \ \mathrm{R_0} \ = \mathrm{A_0^{(c)}} + \mathrm{A_1^{(c)}} \cos \mathrm{E} + \mathrm{A_1^{(s)}} \sin \mathrm{E} + \mathrm{A_2^{(c)}} \cos \mathrm{2} \ \mathrm{E} + \ldots . \\ &\frac{a}{r} \ \mathrm{S_0} \ = \mathrm{B_0^{(c)}} + \mathrm{B_1^{(c)}} \cos \mathrm{E} + \mathrm{B_1^{(s)}} \sin \mathrm{E} + \mathrm{B_2^{(c)}} \cos \mathrm{2} \ \mathrm{E} + \mathrm{B_2^{(s)}} \sin \mathrm{2} \ \mathrm{E} + \ldots \\ &\frac{a}{r} \ \mathrm{W_0} = \mathrm{C_0^{(c)}} + \mathrm{C_1^{(c)}} \cos \mathrm{E} + \mathrm{C_1^{(s)}} \sin \mathrm{E} + \ldots . \end{split}$$

where we have written only the terms whose coefficients are needed.

If the circumference, with reference to E, is divided into j parts, and the corresponding values of $\frac{a}{r}$ R₀ are R⁽⁰⁾, R⁽¹⁾, R⁽²⁾ . . . R^(j-1), then

$$A_{0}^{(c)} = \frac{1}{j} \left[R^{(0)} + R^{(1)} + R^{(2)} + \dots + R^{(j-1)} \right]$$

$$\frac{1}{2} A_{1}^{(c)} = \frac{1}{j} \left[R^{(0)} + R^{(1)} \cos \frac{2\pi}{j} + R^{(2)} \cos \frac{4\pi}{j} + \dots + R^{(j-1)} \cos \frac{2(j-1)\pi}{j} \right]$$

$$\frac{1}{2} A_{1}^{(6)} = \frac{1}{j} \left[R^{(1)} \sin \frac{2\pi}{j} + R^{(2)} \sin \frac{4\pi}{j} + \dots + R^{(j-1)} \sin \frac{2(j-1)\pi}{j} \right]$$

$$\frac{1}{2} A_{2}^{(c)} = \frac{1}{j} \left[R^{(0)} + R^{(1)} \cos \frac{4\pi}{j} + R^{(2)} \cos \frac{8\pi}{j} + \dots + R^{(j-1)} \cos \frac{4(j-1)\pi}{j} \right]$$

$$\frac{1}{2} A_{2}^{(6)} = \frac{1}{j} \left[R^{(1)} \sin \frac{4\pi}{j} + R^{(2)} \sin \frac{8\pi}{j} + \dots + R^{(j-1)} \sin \frac{4(j-1)\pi}{j} \right]$$

Similar equations give the coefficients of $\frac{a}{r}S_0$ and $\frac{a}{r}W_0$.

In fine the following equations result

$$\begin{bmatrix} d\varphi \\ dt \end{bmatrix}_{00} = \frac{m' n}{1+m} \begin{bmatrix} \frac{1}{2} A_1^{(8)} \cos \varphi - \frac{3}{2} e B_0^{(c)} + B_1^{(c)} - \frac{e}{4} B_2^{(c)} \end{bmatrix}$$

$$e \begin{bmatrix} \frac{d\chi}{dt} \end{bmatrix}_{00} = \frac{m' n}{1+m} \begin{bmatrix} e A_0^{(c)} \cos \varphi - \frac{1}{2} A_1^{(c)} \cos \varphi + (1 - \frac{1}{2} e^2) B_1^{(8)} - \frac{e}{4} B_2^{(8)} \end{bmatrix}$$

$$\begin{bmatrix} \frac{di}{dt} \end{bmatrix}_{00} = \frac{m' n}{1+m} \begin{bmatrix} (\frac{1}{2} C_1^{(c)} - e C_0^{(c)}) \sec \varphi \cos \omega - \frac{1}{2} C_1^{(8)} \sin \omega \end{bmatrix}$$

$$\sin i \begin{bmatrix} \frac{d \Omega}{dt} \end{bmatrix}_{00} = \frac{m' n}{1+m} \begin{bmatrix} (\frac{1}{2} C_1^{(c)} - e C_0^{(c)}) \sec \varphi \sin \omega + \frac{1}{2} C_1^{(8)} \cos \omega \end{bmatrix}$$

$$\frac{m' n}{1+m} M_{\rm E} \begin{bmatrix} -2 \frac{r}{a} R_0 \end{bmatrix} = \frac{m' n}{1+m} \begin{bmatrix} -(2 + e^2) A_0^{(c)} + 2 e A_1^{(c)} - \frac{e^2}{2} A_2^{(c)} \end{bmatrix}$$

TRANSITS OF MERCURY, 1677 TO 1881.

PART I.

DISCUSSION OF THE OBSERVATIONS.

§ 1.

Introductory Remarks.

The series of transits of Mercury discussed by Leverrier* terminated with that of 1848. The work of Leverrier on this subject is memorable from the fact that in it was first pointed out the discrepancy between the motion of the perihelion of Mercury as derived from observation and as derived from theory. The existence of this discrepancy, at least when the mass of Venus determined in other ways is employed, has been placed beyond doubt by observations of four transits since the publication of Leverrier's work. Notwithstanding the thoroughness with which the great astronomer treated the subject, there are a number of circumstances which render a reinvestigation desirable. The mere fact that a third of a century of observations, far more accurate than any made in previous times, are now available, is alone a reason for ascertaining whether any modification of Leverrier's results is now possible.

Again, several new questions have arisen which observed transits of Mercury will help to decide. Among these is the question of the uniformity of the earth's rotation. The discrepancies between theory and observation in the moon's secular acceleration, and the inequalities of long period in its longitude, give rise to the question whether the rotation of the earth itself may not be variable. That a slow secular retardation in this rotation exists seems almost certain on theoretical grounds; and it is not impossible that causes may act, capable of producing changes of long period. The question whether the apparent discrepancies in the moon's motion are to be accounted for in this way can best be settled by observation on other rapidly moving bodies.

There are many questions respecting the phenomena of contact, data for the solution of which will be found in the mass of recorded observations of transits of Mercury. Valuable hints may thus be derived in respect to the interpretation and discussion of observed transits of Venus.

Yet another reason for a new discussion is the desirableness of having the results of the theory and of observation so worked out, collated, and compared that the astronomer of the present or future may be able to see how they are to be reconciled

without the necessity of going over the entire discussion from the beginning. The author hopes that the present paper will make this possible.

It is a part of the general policy which the writer has adopted in carrying on this work to secure the co-operation of other astronomers, and he desires to express his thanks to those who have aided him in the collection of materials for the present discussion. Prominently among these must be mentioned Dr. J. A. C. Oudemanns, of Utrecht, who kindly furnished a complete translation of a number of Dutch Memoirs containing observations not found elsewhere. Messrs. R. L. J. Ellery, James Tebbut, and H. C. Russell, of Australia, kindly furnished, in advance of publication, the valuable series of Australian observations of the transit of 1881, made under their direction. Mr. J. E. Hilgard, Superintendent of the Coast and Geodetic Survey, also supplied valuable data from the records of that office. Among them are a great number of American observations on the transit of 1845, which had never been published. Dr. Otto Struve also furnished several unpublished observations made in Russia as well as extracts from the Montpelier Memoirs made by Dr. Wagner.

Most of the heavy work of reducing the observations has been performed by Lieutenant Chauncey Thomas, U. S. N., and Mr. R. W. Prentiss

§ 2.

Authorities for Observations.

Completeness in an investigation like the present requires the use of all data which can add to the precision of the result. In the case of contact observations the phenomena are of such a character that precision can be obtained only by combining as many observations as possible, made by different observers and under different circumstances. For these reasons the available published sources of observations were examined with some care. It was soon found, however, that a limit would have to be set to the number used. In the older volumes of the Berliner Astronomisches Jahrbuch, Monatliche Correspondenz, and Allgemeine Geographische Ephemeriden are great numbers of observations which it is hardly possible to use without suspicion. The range from the most valueless to the best is so gradual that it is very difficult to draw a line of distinction. The embarrassment is increased by the circumstance that the longitudes of the stations are in many cases not known with precision. It was desirable to reduce to a minimum the number of observations likely to be rejected merely on account of their discordance from others, and this again was a reason for leaving out of consideration some observations which might possibly have proved accordant, but which, had they been discordant, would not have been considered entitled to any The rule finally adopted was to retain all observations of known observers and all made at well known observatories, or stations, even when the observer was not known as an experienced astronomer; but, as a general rule, to leave out of consideration those of unknown observers at stations whose longitude would be difficult to determine. Except in the case of the Coast Survey records, and a few Russian observations already alluded to, reliance has been placed entirely upon published sources. The author did, indeed, some years ago make a collection of unpublished observations among the registers of the Paris observatory, but these were unfortunately lost through some accident. A critical examination of them had, however, shown that there

was very little material of value not already published, so that the investigation has probably not suffered much from their loss. The principal published sources are indicated at the commencement of the tabular exhibit of the observations, so that it is unnecessary to repeat them here. Thoroughness has not, however, been aimed at in preparing the bibliographical references, it being deemed sufficient to furnish the reader with the data which would enable him to trace any observations quoted.

§ 3.

Distinction of Phases and Methods of Deducing the Time of Contact from the Observations.

It is well known that different definitions of what shall be regarded as the time of interior contact of a planet with the sun may be formulated. Although, in reality, there can be but one phase of true contact, namely, that of interior tangency of the limbs, yet in practice, owing to the effect of irradiation, the limbs are not seen in their true geometrical outline. It has, however, been very generally considered that when allowance is made for irradiation we shall find two distinct phases of contact, namely:

- I. A phase in which the apparent limb of the sun, as extended by irradiation, and the apparent limb of the planet, as contracted from the same cause, shall be in geocentric contact.
- II. A phase when the light of the sun's limb is first or last seen to completely encircle the planet.

At ingress the phases follow each other in the order here described, while at egress their order is reversed. The first phase is sometimes denominated "apparent contact" or "tangency of limbs"; while the second is commonly known as "true contact" or "formation of the thread of light." The terms apparent and true contact are founded on a theory of the phenomenon which presupposes that the breaking or completion of the thread of light marks the moment of true internal contact, while the apparent tangency of limbs occurs at that interval preceding it during which the planet moves over a space equal to double the enlargement produced by irradiation. The geometry of this theory is quite simple, and, assuming the hypothesis to correspond to the facts of the case, it is quite correct. The theory assumes that, owing to the extreme brilliancy of the sun's limb, the completion of the thread of light can be noted the moment that the planet completely enters upon the solar disc.

In accordance with this view it was generally the custom, previous to the transit of Venus in 1874, to divide phases of contact into the two classes just defined, and to assume that the observer noted one or the other of the two phases. Thus, in Encke's classic work on the transits of 1761 and 1769 we find the observations of internal contact classified under the two heads of "Umkreis in Berührung" and "Lichtfaden." A similar course was followed by Mr. Stone, in his discussion of the transit of 1769, though he put some observations into one class which his predecessors had put into the other.

Now, assuming that observers always did note one or the other of these two distinct phases; assuming also that it could be inferred, either from their statements or from the times given, which phase each observer noted, it would be necessary, in com-

paring observations, to classify the phase and to avoid comparing one phase with another, except after applying the proper reduction.

But all experience concurs in showing that no such distinct classification of the two phases is possible in actual observation. It is true that observers sometimes describe the phase of tangency of limbs and formation of the thread of light as occurring at different specified times. It is also true that, as a general rule, it will be found that these observers who describe the thread of light as fully formed will be found to have noted their times somewhat later [at ingress] than those who describe their observation as that of tangency of limbs.

But this is by no means universal. As a matter of fact, we find the noted times of contact bridging over both phases in such a way that no clear distinction can be drawn. It is also to be remarked that a majority of observers do not define the phase at all; so that it is impossible to infer from their description which phase they observed. The following is perhaps the most conclusive way of considering the subject.

If there are two distinct and separable phases of contact, and if some observers note one phase and some another, then, by examining the times in a great number of transits observed by a great number of observers, we should find in them a tendency to group themselves near two distinct moments, corresponding to the two phases. If, for example, apparent contact at ingress occurs at o' and true contact at 20' then we should find one set of observers giving a result near to o' and another near to 20', while observations at 10' would be fewer in number. To show whether there is any such tendency we have, in a subsequent section, taken all the good observations given in the following pages between the limits 1769 and 1878 and grouped them in the way supposed. It is thus found that there is no tendency to a grouping about any distinct phase, and that the observations all group themselves around a single general mean, according to the usual law of error.

It appears, therefore, that no distinct line can be drawn between the two phases as they have been actually observed by the hundreds of observers in past times.

Associated with the error thus pointed out is another one, which has not been without influence in the discussion of observations. It is that the phenomena commonly known as "breaking of the black drop" at ingress, and which is frequently described by observers as occurring suddenly, is a real and well defined phase. were this so, there would be at least some approximation to agreement among observers as to the time of this phase. But, as a matter of fact which has been pointed out too frequently to need a full explanation at present, there is no such agreement. On the contrary, the divergence of times between the observers of the supposed phase is as wide as between observers of geometrical tangency. Moreover, optical considerations will show that this is nothing more than we should expect. Whether the black drop is or is not present, the moment of the phase thus described is not that at which the thread of light commences, but that at which it became sufficiently strong to be sensible to the eye of the observer. Now, this moment depends very largely upon the state of the atmosphere, the defining power of the telescope, and the contrast between the sun and the sky. Since irradiation implies a diffusion of the solar light, we may expect the phase in question to occur later the greater the amount of this disturbing

cause. But the greater the irradiation the earlier the supposed tangency of limbs will occur at ingress. Hence, with increased irradiation the one phase will occur earlier and the other later than the moment of actual contact.

The general conclusions to which we are led are these: Between the time when, in a field of view with considerable irradiation, the body of the planet would appear as if entirely within the sun, were the limbs of both bodies continued in their circular outlines, and the time when sunlight is seen to completely encircle the planet, there occur a series of phases extending over a period of time which, under unfavorable circumstances, may approximate to an entire minute, and between which no distinct line can really be drawn in practice. With good optical power and fine definition this period of indetermination, if we may so call it, may be so reduced to twenty or even to ten seconds. An observer, taking a general view of the phenomena, and estimating a single moment of true contact from the general appearance; and not from special phenomena, may be expected on the average to note a time somewhere about the mean of the period of indetermination, and therefore a time corresponding closely to true contact. If, however, he clearly sees the formation of a thread of light before the time he assigns, his observation may be assumed to be too late and to need a correction of a few seconds. But when the phase is not described, a mean contact may be assumed to have been observed. At the same time an examination of the observations shows it unsafe to place special interpretations upon the descriptions of observers except those in which they describe the thread of light as having become very distinct.

The conclusion to be drawn from these considerations is that it is for the most part useless to attempt any investigation of phases, and that our proper course is to take an indiscriminate mean of the results of all observers irrespective of their description, except in those cases where there was something clearly different from true contact observed. It may be objected that we thus confound observations of different phases. But the same objection will lie against any observations in which observers do not agree as to the time. Whenever observers assign different times, it is certain that the phases corresponding to these times must be different.

The answer to the objection is that we must let these differences go in with the probable error of the final result. The calculation of probabilities will still apply to the final probable error of the comparison, unless we suppose different observers to have observed systematically on a different plan in different transits. If, for example, we had twenty observations of one transit and twenty of another, and if an observer of each transit was equally likely to observe some phase, A, or some other phase, B, then the chance would be that ten observers observed each phase on each occasion. The probable error arising from the possible unequal division between the phases would be determined on the same principles as the probable error of observations and would be confounded with it. Whatever errors such a course may lead to they will be inherent in the very nature of the subject, and it will be useless to attempt their elimination. Assuming that we take an indiscriminate mean without regard to the remarks of the observers, the standard phase at which we aim will not necessarily be that of true contact but that which would correspond to a mean observation by an infinite number of observers of the same kind as those who actually made the obser-

vations. The adoption of this mean is as legitimate as that of any other, provided the probable error is extended so as to include both that of observation and that of interpretation.

We now reach a difficult question in the treatment Although the course just marked out is inevitable in those cases when we do not know what distinctive phase an observer noted, should we still adopt the indiscriminate mean in the case of observers who specifically state that they observed a particular phase, for instance, that of completion of the thread of light? It might appear that since, in such cases, we know that they observed a phase different from the one aimed at, we should apply a correction to reduce it to the phase. On the other hand it may be maintained that the same phase is also noted by an observer who does not describe the observation, and that, therefore, no account should be taken of differences of descriptions.

On first commencing the work the former system was adopted as being undoubtedly founded on correct principles. Assuming that the observers who describe the completion of the thread of light differed systematically from those who did not, a correction ought undoubtedly to be applied to them, although its omission might not cause a systematic error. But it was soon found doubtful whether, in a great majority of cases, there was any real systematic difference. For example, in some of the older transits several observers describe the planet as being wholly within the sun, thus implying that contact had passed and that sunlight was seen all around the planet, but they sometimes add, to complete the description, that the limbs were in contact, which would negative the hypothesis that contact had passed.

The general impression produced by the discussion was that it was unsafe to apply any special interpretation to the language of observers, and that the different descriptions of phases were merely different ways of describing what was in reality the same thing. An exception should be made in those cases where the description is such as to render it certain that contact had passed, as, for instance, when the line of light seen around the planet was described as a band of sensible breadth.

The course finally adopted does not admit of being reduced to an absolute rule. An observation is thrown aside or corrected when it appears probable that it did not or could not correspond to the general mean. It will be seen by the discussion of the several observations, that in only a few exceptional cases is any correction applied.

One point was, however, strictly adhered to. The acceptance or rejection of the observation was not allowed to depend in any way upon the magnitude of the mean correction which would result to the tabular times. Of course, after the time was concluded upon, it might sometimes be found to need modification or rejection in consequence of discordance. The only cases of such rejection, however, are those of the doubtful times of ingress in the transits of 1740 and 1786. In both these cases it was impossible to obtain a certain result, and the observations are, therefore, rejected. Individual observations were generally rejected when they deviated from the general mean of the other observations by more than half a minute.

Another reason for adhering to the indiscriminate mean is the impossibility in practice of recognizing any observations as those of apparent contact in the sense in which that term has been defined. According to this definition a black drop is sup-

posed to be seen, and the time of apparent contact is that when, if the limbs of the sun and planet were produced through the black drop, they would touch each other. But, notwithstanding the geometric definiteness of the phase, it is, in practice, one which, under the circumstances, it is impossible to observe with any approximation to precision. As a matter of fact it may be doubted whether attempts have been made to note it, unless from some preoccupation on the part of the observer. When, therefore, the observer describes a tangency of the limbs, it cannot be inferred that he means anything different from the average contact.

As a matter of fact the only instance in which the question of this contact came in was connected with the transit of 1878, where there are several cases of geometric contact with black drop intervening.

§ 4.

Longitudes of the Stations.

When, in so great a mass of observations, made in every part of the world, absolute precision is aimed at, the determination of the longitudes of the observers would be the most troublesome and laborious part of the work. It may be doubted whether, with the most elaborate historical research, the position of the observer could in all cases be learned. Happily, the last degree of precision is not necessary, because the necessary probable error of the observations themselves being from 5" to 10", their precision will not be materially diminished by a small error of longitude. Moreover, as a general rule, those observers whose longitude is unknown are otherwise entitled to the least weight. No attempt was, therefore, made at an exhaustive investigation of the observing stations. In the case of towns in France, and sometimes, also, in Germany, the table of positions in the Comptes Rendus was accepted without further discussion. Where there was any room for distinguishing between different points in the city, the cathedral or other central point was generally taken as most likely to be near the place of observation. The places of a few German towns were taken by measurement from the maps in the Hand-atlas of Sohr-Berghaus, published by Carl Flemming, Glogau, 1879. The British Admiralty Charts frequently furnish data for the longitude of ports, but for most maritime stations the longitudes were obtained from data in the Hydrographic Office of the Bureau of Navigation. The observations and researches of Lieutenant Commander Francis M. Green, U. S. N., were of great value in this respect

A table of the adopted longitudes, with the authority from which each was obtained, is appended. It will aid in the application of any corrections which may be required by future investigators.

§ 5.

External Contacts.

Experience seems to indicate that an observation of external contact, under certain conditions, can be made with nearly as much precision as one of internal contact. The observed phase will not, however, be that of tangency of limbs, but that at which the notch made by the planet passes from the stage of visibility to invisibility, or vice versa. This stage depends upon the state of the atmosphere, the eye of the observer, and the quality of the instrument. Yet it would seem that if we regard the effect of the differences which result from these causes as probable errors simply the total probable error will not be materially increased. The fact appears to be that, in day observations upon the sun, the maximum of seeing power is nearly reached with quite a moderate-sized telescope in ordinary states of the atmosphere. No account has, therefore, been taken of differences in telescopic power, etc., except that a few observations, made with evidently insufficient means, have been rejected.

There is, however, one important point to be noted. There can be no doubt that, owing to the progressive improvements in telescopes, and in the art of observing, the phase which would be noted as external contact has continually approached nearer to that of true external tangency. It is, therefore, necessary, in the discussion, to allow for this progressive change. The mode of doing this is described in connection with the formation and solution of the equations of condition.

A very little examination shows that no reliance can be placed upon the older observations of first external contact, and very little upon the recent ones, except where the observers had first practiced upon an artificial transit. As no observations of a distinct class are of value unless they extend through a long period of time, all observations of first external contact have been rejected. Owing to the inferior weight assigned to observations of fourth contact, no attempt has been made to discuss them with the care devoted to those of internal contact. As a rule, the reductions to geometric phase have been supposed the same as in the case of internal contact. Except when the planet passes very near the limb of the sun the error of this hypothesis is insensible.

√ 6.

Explanation of the Tabular Summary of Observations.

The general construction of this summary has been so fully explained in the preceding sections that few additional explanations are necessary. Perfect symmetry of arrangement has not been aimed at, and might tend, in some respects, to mislead because of the impossibility of its according with a series of observations of so miscellaneous a character extending over two centuries.

The first two columns, giving the station and the names of observers, call for no special remark. The third column contains the description of the phase, when any is given. As a rule, the exact language of the observer is quoted, though it sometimes has to be condensed. Sometimes, also, when thus condensed, or when there can be

no doubt as to the exact meaning, his statements are expressed in English. In the majority of cases it will be seen that there is no specific description.

The fourth column contains the time as given by the observer. It is generally apparent time before 1800, and mean time since. No attempt has been made in any case to redetermine the clock correction of the observer, except in a few observations by Wurzlebau, which, however, proved worthless.

The next column contains the reduction to the center of the earth. It is computed from the tabular data as given in the second part. The omitted terms of the second order would rarely amount to one second, and, therefore, need not be taken into account.

The transit of 1782, however, in which Mercury passed very near the sun's limb, is an exception. It was here necessary to make a rigorous reduction to the center of the earth. The details of this reduction are given in the proper place.

Next follows the concluded Greenwich mean time of geocentric contact as deduced from each observation. It is obtained by correcting the observed time for equation of time, reduction to center of earth, and longitude. The three adopted corrections being all given, any error in the reduction can be readily found.

The mean time concluded from all the observations of each transit is given as the result of a separate discussion of each. It was necessary in the case of each transit to discuss the observations upon the system likely to give the nearest approximation to a general mean result.

§ 7.

Classification of Residuals with respect to Magnitude.

The classification of the errors of observed times, with respect to their magnitude, is shown in the following exhibit. The transit of 1782 is omitted. In other cases the numbers given are the differences between each individual observed time and the geocentric time concluded from the general mean of all the observations.

The algebraic signs are so applied that a positive error means that Mercury was too far from the sun's center. Hence, the differences are:

(Computed—Observed) times of contact II.

(Observed—Computed) times of contact III.

By this arrangement similar signs correspond to similar differences of phases of contact.

No allowance is made for obliquity of the path of the planet to the sun's limb.

A P, PART VI---3

Residuals.	Ingress.	Egress.	Total.	Residuals.	Ingress.	Egress.	Total.

-30	0	0	0	>30	9	14	23
>30	9	9	18				

The numbers thus presented show no tendency to divide into groups corresponding to special phases. In order to determine more definitely whether there is any such tendency we divide them into groups of five, the middle group being the sum of -2, -1, 0, +1, +2; the group +5 the sum from +3 to +7, etc. We thus have—

	Magnitude.	No. of errors.	Probable number.
Exceeding —	27 sec.	20	2
	25 sec.	11	6
	20 sec.	15	18
	15 sec.	44	44
	· 10 sec.	77	83
	5 sec.	132	120
	o sec.	147	137
+	5 sec.	89	I 20
+	lo sec.	52	83
+	15 sec.	33	44
+	20 sec.	23	18
+	25 sec.	I 2	6
Exceeding +	27 sec.	29	2

The great difference between the residuals which fall between -3° and -7° and those which fall between $+3^{\circ}$ and $+7^{\circ}$ is striking, but seems to arise partly from the unequal grouping; partly from the excess of positive errors of about $+20^{\circ}$; partly from the excess of instances in which observation of small weight were those of moderate negative residual. It will be remarked that in preparing the table no distinction whatever was made between different classes of results as regards quality; but every residual was enumerated. Hence, any irregularity in the distribution of weights will be shown by an irregularity in the numbers.

To compare these numbers with the probable ones, deduced from the standard law of distribution of errors, we remark that somewhat more than half the residuals are contained in the three middle groups, which again should be considered as comprising all errors between the limits $-7^{\circ}.5$ and $+7^{\circ}.5$. If we include the abnormal residuals which exceed 27 seconds, the limits between which one half the residuals are contained should be regarded as $\pm 6^{\circ}.8$. But considering only those 635 residuals which do not exceed 27 seconds, one half of them are contained between the limits $\pm 6^{\circ}.2$. Actually we have assumed $\pm 6^{\circ}.2$ seconds as the probable error, and thus obtained the probable distribution of the residuals, as shown in the last column.

This method of deducing the probable error does not rest upon a mean of squares of errors, but is based immediately on the definition that the probable error is that quantity for which there is an equal chance that an error shall exceed it or fall short of it. The necessity for adopting such a definition arises when the law of error varies appreciably from that usually adopted, as in the present case.

It is evident, from an examination of the table, that the observations are liable to abnormal errors, since 49 of the residuals exceed 27", while adopting the usual law of

error the probable number should be only 4. Quite likely the abnormal error, in many of these cases, arises from such mistakes as those of a minute in the recorded time. But I think that, for the most part, they arise from the unfavorable circumstances under which observations are frequently made. It is evident that if we have a collection of observations of different degrees of probable error, in which, however, there is no way of distinguishing those of great probable error from those of small probable error, the law of the errors will not be that usually adopted, but there will be a comparative excess of large residuals. It is also evident that in such a case the arithmetical mean does not necessarily give the most probable result. For, in the case of an observation of large residual, there is evidently a preponderance of probability that it belongs to a class with large probable error, and therefore should be assigned least weight. This principal has, to a certain extent, been indirectly applied in deducing the times of geocentric contact from observation. When a result differed from the general mean by a quantity much more than half a minute it was rejected. The above table seems, however, to indicate that all residuals exceeding 25" should be rejected, except in cases where the other observations on the same transit were worse than the average.

That any general collection of observations of transits of Mercury must be a mixture of observations with different probable errors was made evident to the writer by his observations of the transit of May 6, 1878, which may be here described as an illustration of the subject.

The instrument used was a 4-inch telescope not moved by clock-work, and, therefore, somewhat difficult to manage. At ingress the definition of the sun's limb was fairly good, though there was a slight distortion in the figure of the planet about the time of internal contact. About the time of contact there was an interval, which I should roughly estimate as probably not less than 6° nor more than 10°, during which it was doubtful whether contact was or was not past. The middle of this interval was therefore taken as the time of contact, with an error which almost certainly could not exceed 5°. About 12° later the band of light between the limb of the sun and planet was clearly of sensible breadth. It could therefore be asserted with entire confidence that the contact took place several seconds before the last recorded moment. Yet a large number of observations gave a later time than this, when all were reduced to the center of the earth. It may, however, be remarked that the time of true contact as noted agreed closely with the general mean.

At egress, however, the circumstances were entirely different. The sun shone through a thin cirrus cloud which, although it did not seem to disturb the limb materially, yet produced such a blurring as at times almost to obliterate the view of the planet. Under these unfavorable circumstances a time of probable contact was noted. But half a minute later, during a few seconds of somewhat better definition, it appeared doubtful if contact had really taken place. Bad definition immediately followed, and the attempt to note contact had to be given up. Some seconds later the sun shone with nearly its full brilliancy; the planet then appeared to form a notch in the sun's limb the shape of the letter U, the length of which was fully double its breadth, thus showing distortion in an extreme degree. Had this state of things occurred a

minute earlier a well formed black drop would no doubt have been seen. Before the planet went off the sun its limb again became so disturbed that external contact could not be noted.

Hence it was impossible to have recorded a time of internal contact at egress which would not have been liable to an error of half a minute or more. Even during the time of best definition between third and fourth contacts an observed time would have been liable to an error of from ten to twenty seconds. And I am persuaded that at this time the sun was not more disturbed than it very often is in observed transits. The conclusion I therefore draw is that if it were possible to select from a collection those observations made under the most favorable circumstances, and by observers fully prepared for the phenomena, we might either reject, or assign but small weight to, all the other results. Unfortunately, it is, in most cases, impossible to select such observations. Still, it is not likely, in the method of treatment actually adopted, that the systematic error is considerable.

The main conclusion to be deduced from the tables is, however, that there are no distinctive features of contact which are actually noted by observers. The phases merge into each other by insensible gradations, and the mean phase is got more frequently than any phase differing from it by so much as 5". Especially no tendency can be seen to observe anything which we may consider true contact, apparent contact, breaking of the ligament, etc., at any definite time. It may be advisable in some cases to correct an observation which the observer particularly describes as one of a special phase. But even this must be done with caution.

Tabular Summary of Observations with their Reductions.

In comitatu Lan- castria.	Townley	IV. Total Egress	2	54	0	- 8		••••	••••	••••	Do.

GALLET'S observation may be rejected without discussion, his time being certainly more than a minute after last external contact.

Townley's time and longitude are so uncertain that his observation has not been used.

Considering the errors of the tabular times as not exceeding half a minute, it would seem that both of Halley's phases at ingress are a minute or more late, and both those at egress perhaps a minute too early. The most plausible explanation seems to be that, with his bad telescope and inexpertness in observing, he did not see Mercury at first contact until long after it had began to indent the solar disk, and that Mercury did not appear "totus intra Solem" until the thread of light had reached a considerable thickness. At egress the same causes would produce the reverse effects, though probably in a less degree.

These observations can, therefore, be combined with those of other observers only when this probable source of error is eliminated.

1690, NOVEMBER 10.

[Equation of time, — 15^m 40^s.]

Place.	Observer.	Contact and description.		Local app. time.		Red. to geocentric phase.	Greenwich mean time of geocen- tric contact.	Authority and remarks.
Canton	Fontenay	Sortie certaine et entière	h .	m. 18		8. -22.5	h. m. s. 19 28 52	Paris, vii, pt. ii, p. 870.
Nuremberg	Wurzelbau	Merc. postquam undulanti limbo Solis ad Min. temporis adhæ- serat exiit.	8	24	45	-61.2		P. T., xvii, p. 485.

According to Wurzelbau, his observation was made at 8^h 36^m by his clock, and the mean of four altitudes following it gives the correction — 11^m 15^s. The result is, however, several minutes in error, and the observation is not worth discussing.

Nothing is said of the instrument with which Fontenay's observation was made, but his remark, "Il a paru toujours dans le Soleil comme une tache noire et fort ronde," implies a good instrument. The planet appeared half emerged at 3^h 17^m 5^s app. time.

1697, NOVEMBER 2.8.

Contact II, 21 10 30 III, 23 48 51 IV, 23 51 50

1740, MAY 2.4.

[Equation of time, -3^m 25^s.]

Place.	Observer.	Contact and description.	Local app. time.	Red. to geocentric phase.	Greenwich mean time of geocen- tric contact.	Authority and remarks
[Cambridge, U.S	Winthrop	diameter entered Almost within	h. m. s. 4 54 59 5 0 40	#84.3	h. m. s. 9 37 28 9 43 9	P. T., xlii, p. 572.

This observation, rude and uncertain though it appears, is noteworthy, not only as being the first made on a May transit, but as belonging to that May transit in which the distance of centers was greatest. It may also be remarked that estimates of the kind here given are more accurate in comparison with contact observations than is commonly supposed. We may, therefore, see what conclusions may be drawn from them. In the first place, the tabular interval between contacts is 8^m 28^s. Three-fourths of this being 6^m 21^s, the reduced time of internal contact would be 9^h 43^m 49^s. The general character of the intervals between observed contacts, as estimated by observers in those times, indicates that they often lost sight of the planet when one-fourth of it was still on the disk. The general conclusions from Professor Winthrop's observations may, therefore, be summed up as follows:

From first estimate, time probably earlier than 9^h 43^m 49^s.

From second estimate, time certainly later than 9^h 43^m 9^s.

Therefore, if we assume 9^h 43^m 29^s as the reduced time of internal contact, the probable error of the result, mistakes aside, would seem not to exceed 20^s.

The ulterior discussion, however, shows a probable mistake in the time, since, at the last recorded moment, when Wintheop thought internal contact had not quite arrived, the contact would seem to have been decidedly past.

The danger of assigning special interpretations to the language of the observers may be seen in the case of Maraldi, who describes Mercury as wholly entered, while, at the same time, its limb touched that of the sun, and this a second after Short, at London, saw the thread of light fully formed. It would seem that in all cases the observers at ingress noted a time about that of true contact. The time required for the formation of such a thread of light as that described by Short would be 4° to 6°. If we subtract 5° from his time we shall have 20h 14m 22°. Then, the mean of all the five observations will be

In the case of third contact there is nothing to indicate any separation of phases. The general mean of all the observations is

Rejecting Maraldi's doubtful observation, we have seven observations of last contact, the mean of which is

The actual computed interval between the last two contacts is 121°. If we suppose the observation of Cassini the son correct, he saw the planet 20° after the mean of the other observers, and the true internal contact could not have arrived until after 0^h 45^m 12°. But, it seems hardly likely that the other observers should have lost sight of it so soon were his observation correct.

1753, MAY 5.9.

^{*} The observor notes this phase as observed very accurately with a power of 75. There would seem to be some mistake in his time.

The discordances among the times of internal contact are such as to render it difficult to fix upon a definitive moment as that given by observation. An indiscriminate mean of the whole, rejecting only the doubtful external contact by Bouguer, gives

But, in reality, the observations should not all have the same weight. If we take the six best known observers, Cassini, Le Gentil, Delisle, Short, Bevis, and Bird, the mean results are,

In this case, the times of internal contact still have a range of 28 seconds, while the agreement in the case of external contact is fairly good.

Looking at the general agreement among the observers of external contact, it can hardly be doubted that Mercury was entirely off the sun before 9^m 0^s. If this be so, there must have been an error of half a minute or more in the times of the observers at Haarlem and the Hague. One of these is entirely unnamed, the other was not an astronomer. Their results may, therefore, be rejected without question. The description of his observation given by Lulofs would indicate that it was very exact. As his time is the latest of all, and 40 seconds later than the mean of good observers, we are obliged to reject his result from the suspicion of an error in his time. The Naples observation may be placed in the same category.

We have left the five observations already cited by known astronomers, and eight others by comparatively unknown ones. For internal contact the mean of these eight results is,

An indiscriminate mean of all but the Dutch observers gives 22^h 8^m 44^o.5 as the time of external contact. The following times seem the most probable from all the observations:

1756, NOVEMBER 6.7.

[Equation of time, — 16^m 3^s for ingress; — 16^m 2^s for egress.]

Place.	Observer.	Contact and description.		Local app. time.		Red. to geocentric phase.	Greenwich mean time of geocen tric contact.		erio comença	Authority and remarks.	
			h.	m.	s. ,	8.	h.	m.	8.		
Pekin	Hallerstein	Ingressus totus	21	30	30	-33	13	28	6	St. P., N. C., ix, 503.	
	Gaubil		21	31	54	-33	13	29	30	Paris, 1758, p. 135.	
	Hallerstein	Ş cæpit egredi ex ⊙	2	54	22	+ 8	.8	52	40		
	Amiot	Attouchement inférieur	2	54	20	+ 8	÷	52	38		
	Gaubil	Commencement du sortie	2	54	25	+ 8		52	43		
	Hallerstein	Egressus totus	2	56	6	+ 8		54	24		
	Amiot	Sortie totale	2	56	4	+ 8		54	22		
	Gaubil	Fin de la sortie	2	56	31	+ 8	!	54	49		

It is remarked by Le Verrier that the observations of Gaubil and Amiot give a semi-diameter of the sun so small that he rejects them entirely. Those of Haller-stein he does not refer to. The discordances will be seen from the circumstance that the tabular interval between external and internal contacts is only 1^m 39^s, while that between internal contact and the least visible phase at external contact must be 10 or 20 seconds less. It is, therefore, certain that contact III was observed too early by all the observers.

The discordances at ingress are yet more strongly marked. Arranging the statements of the three observers in chronological order, they are:

- h. m. s.
 21 29 15; HALLERSIEIN, primum visus.
 - 29 49; GAUBIL, commencé à voir Mercur.
 - 30 30; HALLERSTEIN, ingressus totus.
 - 30 51; GAUBIL, le centre sur le bord du Soleil.
 - 31 12; AMIOT, à moitié entré.
 - 31 54½; GAUBIL, Mercur. tout entré.

GAUBIL and AMIOT observed together; HALLERSTEIN in an entirely separate place. GAUBIL and HALLERSTEIN had 14-foot telescopes, AMIOT an 8½-foot telescope. That GAUBIL and AMIOT saw Mercury only half entered more than a minute after its appearance upon the disk can be attributed only to badness of their telescopes.

The best course seems to be to reject all the observations except those of last external contact, which are less affected by telescopic irradiation. Giving half weight to Amor's observation, the mean result will be,

Contact IV, 18h 54m 34s.

[Equation of time: Ingress, - 15^m 51^s; Egress,

Among all observed transits this one is remarkable for the nearness of Mercury to the sun's limb, the least distance of centers not being 30" less than the sun's semi-diameter. The interval between internal and external contacts was more than seven minutes, and a good opportunity was, therefore, offered for studying the phenomena of contact.

At Paris ingress occurred late in the afternoon, and egress only a quarter of an hour before sunset, so that the sun's limb was much disturbed by atmospheric vibrations. The American observations were made under much more favorable conditions, so that, if an absolute result were alone aimed at, they would be entitled to greater weight. But what we really want is not so much the time of mathematical contact as a time corresponding to the general average phase noted by other observers in other transits. Now, an examination of the descriptions of contacts shows that in this, as in the preceding transits, it seems impossible to discriminate with certainty between different phases of internal contact merely from the descriptions of the observer. Thus, Mechain describes "entrée totale" two minutes before any one else saw the thread of light. For ingress, one course will be to reject Cagnoli's observation entirely, as clearly in error, and take an indiscriminate mean of all the others. This will give

On the other hand, we have been led to suspect that, in previous transits, observers with bad telescopes were apt to observe internal contact too late, because the

thread of light would not seem complete till after it had attained a considerable thickness. Should we reject the observations of Wallot (int. cont.) and Le Monnier, where it is evident the thread of light cannot have been observed, we should obtain 2^h 42^m 29^a as the time of contact. On the whole, however, it seems better, for the present at least, to accept the indiscriminate mean.

At the time of egress the sun had nearly set to Paris, so that the observations there were made under very unfavorable circumstances. The American observations being made nearer noon, deserve more careful consideration. In treating them, it seems advisable to take the probable skill of the observer into account. Wintheor's observation deserves the highest weight, because of his care in describing three well-marked phases. There seems little doubt that the time of contact from his observations should be placed between the second and third phases; perhaps midway, but more likely one-third of the way from the second to the third.

Next in order should come the observations of the practiced observers, WILLIAMS, WILLARD, and RITTENHOUSE, though, as they do not describe the phenomena, their observations have less weight than those of WINTHROP. We may, therefore, take for the three best results,

There remain five results of comparatively unknown American observers, including Paine, who had but a small telescope. The indiscriminate mean of their times is

The indiscriminate mean of the six Paris observations is

$$3^h 49^m 35^s (3)$$

If we reject Cagnoli and D'Ayen, the mean of Cassini, Wallot, Mechain, and Le Gentil is

Considering the extreme obliquity of the motion, the accordance of these four mean results is quite satisfactory. In combining them, I shall assign

To (1) the weight 4.
(2) the weight 2.
To
$$(3) + (4)$$
 the weight 1.

giving 3^h 49^m 24ⁿ as the concluded time of third contact. For the fourth contact we

can do no better than take an indiscriminate mean of the eight American observations. We thus have, for the concluded times of the geocentric contacts,

In reaching this result, however, we have used only the differential reduction to geocentric time, computed by the usual formulæ. But, in a transit occurring so near the sun's limb as this, the differential reduction will not be sufficiently accurate. A rigorous computation of the times of contacts has, therefore, been made for Paris and Cambridge by formulæ given hereafter, and these times have been compared with the geocentric times. The principal steps of the process are shown in the following table:

		act II. M. T. 2 ^h .7.		nct III. M. T. 3 ^h .85.		nct IV. M. T. 3 ^h .95.

At ingress about twice as many observations were made in Europe as in America. We may suppose the correction, —12°, applicable to all the European observations, and —8° to all the American ones. This will diminish the general mean by 11°.

At egress the weights of the Paris and Cambridge observations were in the ratio A. P. PART VI—5

of 1:6. This will give +13 seconds as the correction. We thus have, for the concluded geocentric times:

Contact II, 2 42 6 III, 3 49 37 IV, 3 56 6

1786, MAY 3.7.

The fixing of a definite time of ingress from the four discordant observations is very difficult from the fact that Rumowski, whose description is clear and exact, saw the ingress notably sooner than any one else. He says:

"Momentum pro contactu interno in introitu assumtum est a me illud, cum inter undulantes et tremulos limbos filum lucidum mihi sese obtulerit, id circo realis contactus aliquot minutis secundis a me observatum præcesserit necesse est."

Granting the correctness of the observation, this conclusion is sound, and geocentric contact must have occurred decidedly before 14^h 5 ^m 25^h.

On the other hand, the sun was only about 8° above the horizon at St. Petersburg, while at Bagdad its altitude was considerable. Against this, however, must be placed the consideration that the longitude of Bagdad is uncertain by some seconds.

At Mitau the sun was still lower than at St. Petersburg, and the observer gives no description. The observation may, therefore, be passed over.

Some light may be thrown upon the results by the observations of external contact We have:

Tabular interval between contacts I and II - - 4 16
Rumowski estimated bisection of disc at - - - 16 59 44
INOCHOLZOW saw "contactus primus sive externus" 17 0 6

There is clearly a blunder on one side or the other; probably an error of one minute. If we assume Rumowski to be correct we have nothing better to do than accept his result, and put

If, however, we assume an error of 1^m in Rumowski's time, we may assign equal weight to him, Beauchamp, and Inochodzow. We shall then have

We cannot decide a priori between these hypotheses.

Though the observations at egress are also unusually discordant, there is less doubt about the result. In the first place, an indiscriminate mean gives

Examining the observations critically, we may reject the observations of D'Cesaris and Toaldo on suspicion of an error of one minute, and the doubtful observation of Köhler. Moreover, we may suspect the two London observations to be but one, from the absolute identity of both third and fourth contacts. We may also assign superior weight to the observations of Rumowski, Inochodow, Prosperin, and Messier. The mean of their times is 20^h 21^m 27^s. The mean of the remaining unsuspected twelve observations is 20^h 21^m 28^s. We therefore have

The "Washington college" observations are assumed to have been made at an institution of that name in Chestertown, Md.; but this is purely conjectural. No locality is mentioned. Their systematic discordance indicates an error in the time, and they are not used.

The ingress affords a case in which the astronomer must feel in doubt what conclusion ought to be drawn from the combined observations. Supposing the observations of Messier and Mechain correct, the true contact must have occurred before oh 53^m of. But every one of the other observers assigns a time later than this. The general mean results are:

True contact, from observations of Messier and Mechain - 0 52 56 Indiscriminate mean of all the observers - - - - 0 53 8

If we employed no transits except those in which we could deduce a time of true contact from the descriptions of the observers, we should, no doubt, use only the first

result. But, being obliged, in many cases, to use indiscriminate means, the last result is not to be neglected. On the whole, it would seem that the mean of the two is about the phase we want.

The third contacts offer no difficulty. In the fourth we give double weight to Willard and Rittenhouse. The concluded results are, therefore,

M. m. i.
Contact II, 0 53 2
III, 5 44 12
IV, 5 46 8

1799, MAY 7.1.

Equation of time: Ingress, — 3^m 43^a; Egress, — 3^m 44^a.

The discordances at ingress are striking, but do not prevent us approximating to a definite result. In the first place, we have four observers who distinguish between

inner contact and thread of light. From these we may reject TRIESNECKER, from the extraordinary interval of 61 seconds between the phenomena. Taking the mean between the times of the two phenomena in the other cases, the results for contact II are

We note also that the mean of the three intervals between the two phenomena is 6°.

Next, we may take the well-known observers who do not describe the phenomena, Burg and Vega, who noted the thread of light, and v. Beeck, who seems to have made a satisfactory observation. From the times of the three last named we may subtract 5° to reduce them to probable true contact. We then have the following results:

•			h.		
			n.	m.	8.
Rumowa	3KI	-	2 I	9	25
Bürg	-	-		9	43
VEGA	-	-		9	48

Bode	-	-		9	44
Bouvar	D	-		9	28
LALAND	E	-		9	57
DELAME	RE	-		9	67
v. Beec	K	-		9	15
		_			
Mean	_	-	2 I	9	4 I

Should we reject the three Paris observations and that at Amsterdam, on account of their discordance, the mean result would be

From the remaining observations we may reject those of Kremsmiinster and Leipzig without question, as well as that at Utrecht, where clouds rendered the observation late. The indiscriminate mean of the remaining ones is

But there is little doubt that the Breslau observations should be rejected from any mean. We should then have

The different classes of observations seem to group themselves so clearly around the mean 21^h 9^m 42^s that we may adopt this as the time of contact.

Treating the observations of egress in the same general way, we note that three observers observed separately the formation of the black drop and the internal contact. Moreover, the means of their times agree almost perfectly, and give

Other experienced observers, who do not describe any phenomena, give the results:

		h.	m.	8.
Rumowski	-	4	30	27
Воре	-		30	3 I
BURKHARDT	٠ -		30	29
Messier -	-		30	49
DELAMBRE	-		30	27
Bouvard -	-		30	2 I
MASKELYNE	-		30	26
Wilson -	-		30	16
NISBET -	-		30	36
T. F	-		30	30
TROUGHTON	-		30	22
Mean -	-	4	30	29

The indiscriminate mean of the remaining twelve results is

But there is little doubt that we should exclude the three observations at Breslau. The mean result will then be

The mean result to be adopted may be fixed at 4^h 30^m 32^s.

For fourth contact we reject the observations of Hoffman, Junghitz II, and Ender, as well as the doubtful ones at Hamburg. We thus have the following geocentric times for the three contacts:

1802, NOVEMBER 9.0.

The discordance between Hodgson's observation of ingress and the observations of Rümker and Brisbane is embarrassing. If, as appears to be the case, Brisbane never published his observations himself, it is likely he assigned them little weight. As a combination of Hodgson's observation with the other two is out of the question we must for second contact adopt

with a suspicion that it may be too late.

For third contact there seems no better course than to combine all, giving greater weight to RÜMKER and BRISBANE. The result,

seems most probable.

The fourth contacts observed at Calcutta again are troublesome, because it hardly seems probable that the planet should have disappeared from sight more than a minute before external contact. We shall therefore reject their results. The mean of the remaining three observations is

All these results must be regarded as more doubtful than usual.

Studying the results for ingress we may act on the following conclusions:

- 1. No doubt of a mistake of 10^m in copying the Reval observations.
- 2. As RÜMKER considered his observation too early we may reject it.
- 3. H.'s observation through clouds should be rejected; his certain one retained.
- 4. Davis's observation is probably im in error, but as he gives no description, cannot be safely corrected. We therefore reject it.
- 5. ALEXANDER'S two observations should be separately retained, the sun being high and his description clear.

The mean of the 25 observations of first internal contact is 4^h 23^m 50^e.

At egress Davis describes his observation as very uncertain, and the time that of first elongation of the planet. The average correction for this phase is +10°; we may apply this and assign ½ weight to his results. We may also assign double weight to MITCHELL, of Nantucket, and the BONDS.

From Bache's diagram I judge the most probable time of contact is found by applying + 5° to his first observation. The mean, with these modifications, becomes 10^h 49^m 7°. We thus have,

For fourth contacts we may include ALEXANDER's two observations separately and reject the Portland observation as certainly in error. We then have

The observations of second contact are so scanty and uneven as to require some care in treatment. Knorre's observation is indicated as very uncertain, which might well be, as the sun had risen only 23 minutes before, and its altitude was less than 4°. Owing to this, and its discordance, the observation has been rejected. Oudemanns observed on a screen, and lost the moment of actual contact by a cloud. But he was able to obtain what he deemed a satisfactory result by subtracting 13°.8 from the time when he concluded the thickness of the thread of light to be 1". The best combination appears to be to assign weights as follows: Scott 1, Abbot \(\frac{1}{3}\), Todd 2, Oudemanns 1. The mean result will then be 17h 20m 16°.

Among the third contacts the Edge Hill observation is clearly too late, while it may be assumed that the observation of LASSELL is affected by an error of one minute. We might suspect the same error in Werdmüller were it not that his observation of external contact cannot be thus reconciled with the others. Correcting Lassell, and rejecting Jee and Werdmüller, the agreement is excellent and the general mean result is 21^h 18^m 20^s.

The concluded results now become-

A. P., PART VI----7

TRANSIT OF NOVEMBER 4, 1868.

In this transit the attention of observers was attracted to the optical phenomena of contact more fully than in any preceding one. Although it had been long wel understood that the outlines of Venus and the sun did not always preserve their geometric form at the time of contact, few observers were conscious of the necessity of noting and describing any distortion that might be perceived, and of stating the exact appearance of the planet at the moment cited as the time of internal contact. In a paper published in the American Journal of Science and Arts for July, 1870,* I have given a collection of the principal observations of egress made at this transit, arranging them in the order of reduced geocentric time. A similar but more complete table is also given by André in his paper on the observation of contacts in transits of Venus and Mercury.†

For our present purpose, the best course seems to be, so far as egress is concerned, to follow the same plan, tabulating the observations in the order of reduced geocentric time, and indicating the observer's description of the phenomena in each case. In general, no distortion was observed at stations where the altitude of the sun was considerable and the atmosphere steady. In such cases there would be no especial phenomena for the observer to describe, and the time noted would naturally be that of true contact.

Maidenbead	Lassell	·	21	0	37	- 1.0	1		36	Greenwich mean time.
Wimbledon	Penrose	Thread of light interrupted	21	0	53-7	- 1.4	!		52	Greenwich mean time.

The Peking observation is given in so confused a manner that no use has been made of it. The remaining two observations of contact II seem entitled to equal weight.

For contact III there are several sources of doubt connected with the San Fernando observations; they are, therefore, regarded as forming but a single observation. The Wimbledon observation may be rejected as certainly affected with some abnormal error. The mean of the remaining results is taken without discrimination, since no discussion would materially affect the general result to be derived from the whole.

No separate reduction of fourth contacts has been attempted, but the mean result has been taken from the paper by Wolf and André already cited. The concluded results are:

TRANSIT OF 1878, MAY 6.

Among these observations, the following may be set down as too late to correspond to any observation of contact as usually made, namely: Mohn, "Sichere Trennung"; Galle and Neugebauer, "Völlige Trennung"; Förster, "Breiter Lichtfaden"; Becker, Lohse, "contact certainly past."

Nearly the same thing may be said of the "Deutlicher Lichtstreifen" of BECKER and Peters, but as we have been under the necessity, in other transits, of retaining observations of the threads of light, we may include these in the same class, and in each case, take the mean of the two times given.

In all the remaining cases we may take the indiscriminate mean of all the separate times noted, with the following exceptions.

The observation of Lukas, at Vienna, is rejected, owing to the totally insufficient

optical power employed. The mean of Weiss's three times is taken as a single observation. Half weight is assigned to the doubtful O-Gyalla observations of Horváth and Cvet. We thus find:

Mean result of 73 European observations, 3^h 15^m 47^s.3, G. M. T.

Let us now compare this result with that of the American observations. In Appendix II to the Washington Observations for 1876 is an exhaustive discussion by Professor Eastman and Mr. H. M. Paul of 109 observations of this transit made in the United States. The classification of the times of the different phenomena, as described by the observers, is especially complete and instructive. I therefore transcribe the mean results, reduced to Greenwich time.

CONTACT II.

					h	Times.	No. of obs.
I.	Geometric contact with black drop -		-	-		15 26.7	4
2.	Phase I		-	-		31.7	8
3.	Geometric contact without black drop			-		42.6	3
4.	Geometric contact with no statement of	blacl	k di	rop		42. 9	9
5.	First glimmer of light behind planet		-	-		1 49.4	I 2
6.	Phase II		-	-		50.2	16
7.	No description of phase		-	-		51.8	27
8.	Breaking of ligament or black drop -		-	-		52.8	7
9.	Closing of line of light		-	-		57.0	t I
10.	Phase III		-	-		61.2	14

In this table phases I, II, and III refer to the appearance of the planet at three different times, as shown on a large diagram which had been circulated among the observers.

Phase I, in this diagram, represented the planet as it would appear 12° before first interior contact, the cusps being separated by nearly one-half the diameter of the planet.

Phase II represented the appearance of the planet at the exact moment of true interior contact.

Phase III represented the appearance 12° after contact, a broad line of light being formed between the planet and the limb of the sun.

The size of the diagram was such that when placed at the distance of half a mile, the angular magnitude of the planet on the diagram would be the same as that of the real planet in the heavens.

Mr. Paul's discussion, however, showed that the observations of these outside phases, I and III, were much less accurate than in the case of ordinary contacts, so that they had to be rejected entirely. But he also rejects phase II, which is that of true internal contact, for reasons which he does not fully state. The only phases which he retains in his discussion are those of $\frac{1}{2}$ (5 + 9), 8 and 7. From these he deduces

Whatever we may say of the correspondence of this result with the time of true contact, it is cannot be considered as the time to be compared with observations of previous transits by other observers. Since we have been obliged to include all observations,

those in which phases were not described as well as those in which phases were described, our proper course is to take the same sort of a mean which would have been taken had the observations been treated in the same manner and not classified as they are. Let us take up the phases in order.

The four observations of geometric contact with black drop, occurring as they did 5° before phase I, when the cusps were separated by more than the radius of the planet, should be rejected entirely if anything like true contact is sought for. But it may be that they correspond to observations in other transits, and therefore should be retained.

Phase I and III, for reasons already given, may be thrown aside, although their mean corresponds closely to the general mean of the observations. All the other observations seem to correspond closely to the usual observed phases of contacts: the general mean may, therefore, be taken.

It is, however, to be remarked that Mr. Paul's means, as given above, are taken by weighting the observations according to atmospheric and other conditions. Although this process has not been employed to any considerable extent in the discussion of the preceding transits, we may adopt Mr. Paul's weighted results as being better, or at least, no worse than indiscriminate means, even for purposes of comparison. We therefore first give to each of the results, from 3 to 9, inclusive, a weight proportional to the number of observations on which it depends, and thus obtain the first result which follows. Next, we show the result when the four observations of geometric contact with black drop:

```
Contact II, 3 15 50.7, 85 obs. (rejecting class 1)
15 49.6, 89 obs. (retaining class 1)
15 47.3, 73 obs. (European)
```

What mean between these results we should choose is largely a matter of judgment. That the means of two so large bodies of observers should differ by 3 seconds shows it hopeless to expect a probable error of less than 2 seconds in the best possible results from observation. In view of the fact that the American observations were generally made with the sun at a higher altitude than in Europe, I have taken 3^h 15^m 49^s.2 as the most probable mean.

CONTACT III.

For egress we have the following results from Mr. Paul's tabular summary:

				Times.	No. of obs.
		•		h. m. s.	•
I.	Phase III			10 43 15.7	5
2.	Phase II			36.4	5
3.	Geometric contact with nothing about	black	drop	36.6	8
4.	Formation of ligament or drop			39.2	. 01
5.	Breaking of line of light			39.6	7
6.	Geometric contact without black drop			39.8	2
7.	No description of phase			42.2	27
8.	Last glimmer of light			42.8	8
9.	Phase I			52.3	5
10.	Geometric contact with black drop -			- 57.7	7

The curious reversal of the supposed normal order of phases, geometric contacts being noted earlier than last glimmer of light, is noteworthy. The early occurrence of "phase II" (true contact) is also remarkable. Whatever conclusions we may draw from these anomalies, the only course open to us is to take a mean of those phases which we may suppose to correspond to phases observed in preceding transits. We therefore reject phases I and III. It is doubtful whether geometric contact with black drop should be retained or rejected.

We may accept the mean of the two as the result to be accepted.

For external contact an indiscriminate mean is taken in the usual way, rejecting a few observations with very insufficient optical power. The results then are:

TRANSIT OF 1881, NOVEMBER 7—Continued.

Guided by the light thrown on the case by previous observations, we shall endeavor to deduce a time of contact from the statements of each observer, and assign weights according to the apparent certainty of the results.

Whether Mr. Ellers's "good" internal contact is to be regarded as a true mean contact it is difficult to say: The breaking of the black drop may be regarded as certainly later than mean contact. On the whole, the most probable result seems to be that obtained by adding to the time of the first observation one-third of the interval between it and the second. This will give 10^h 18^m 47ⁿ, Greenwich time.

From Mr. White's observation we may subtract 5°, giving 37°.

Moerlin's "complete separation" is clearly too late.

TEBBUTT's description is excellent; his mean time is 40°.

During the 10°, from 24° to 34°, Russell saw the thread of light formed and broken several times. This is what should take place in the situation corresponding to true contact. We may, therefore, take 29° as his result instead of 34°.

The four observers following Russell give no indications for judging their results. Wright is so obviously too early that it is doubtful whether his result should not be rejected. A mean course will be to assign him half weight. The mean result of the four will then be 37°.

BLADEN'S two descriptions clearly bound the possible times of confact. The mean 32' seems good. The next two results may also be accepted unchanged.

With ROCKWELL'S Honolulu observation we have the same trouble as with WRIGHT'S at Sydney. In doubt whether to reject it, we can assign it only small weight.

We now have the following single or combined results for probable mean contact II: •

						h.	m.	8.	Wt.
Ellery -	-	-	-	-	-	10	18	47	2
Wніте -	-	-	-	-	-			37	2
Теввитт	-	-	-	-	-			40	3
Russell	-	-	-	-	-			29	I
Four other	ob	ser	ver	3	<u>-</u> ·			37	3
Couder -	-	-	-	-	-			34	2
Brooks -	-	-	-	-	-			34	2
ROCKWELL	-	-	-	-	-			10	1/2
Holden	-	-	-	-	-			53	2
Burnham	-	-	-	-	-			33	2
Mean	-	-	-	-	-	10	18	38	

Of the third contacts, only the following call for special remark.

Mr. Ellery's "thin flickering line" was probably the result of atmospheric softening of the thin line of light just before contact, and so not to be regarded as a true contact of any kind.

TURNER'S description corresponds accurately to a true contact.

TEBBUTT's description close limits the time of contact.

BLADEN's result seems valueless. The images were too bad to permit of an obser vation of contact.

With Rockwell's we have the same trouble as at ingress, only he is now late. We should, perhaps, treat his observation in the same way as at ingress.

In the combination we give double weight to Tebbuit and Russell. The mean result is then 15^h 35^m 54^s.

The results for geocentric contact then are—

PART II.

COMPUTATION OF TABULAR ELEMENTS.

LEVERRIER'S tables of Mercury and the sun have been adopted as the medium for obtaining the results of the preceding observations, in so far as the elements to be corrected depend upon the relative heliocentric positions of Mercury and the earth. The method of deriving the times of contact and other results from the tabular positions is not the usual one, since the computation of the geocentric place of the planet is entirely dispensed with. Not only would the computation of this place involve considerable additional labor with great liability to errors, but the symbolic expressions of the corrections to the theory would also have been more troublesome in computation. A method has, therefore, been adopted which is founded on Bessel's theory of eclipses. By this method the time of contact is defined as that when the observer is on the conical surface touching the planet and the sun. Of the two circumscribing cones, that whose vertex is between the interior planet and the earth will correspond to internal contact, and that whose vertex is between the planet and the sun to external contact.

Į Ι

Determination of times of contact during transits of an inferior planet by the heliocentric method, using the conceptions of Bessel's method of eclipses.

By this method the time of contact is fixed as that when the observer is upon the surface of one of the two shadow cones touching the sun and the planet. The axis of the cone is the line joining the centers of the sun and planet. The fundamental plane of reference, or the plane of XY, passes through the center of the earth perpendicular to the axis of the cone.

The axis of X in the present case is formed by the intersection of the ecliptic with the fundamental plane, its positive direction being toward the west or the opposite of that in which planets are moving. The axis of Y is, as usual, toward the north.

Let us put:

- r, b, l, the heliocentric radius vector, latitude, and longitude of the planet Mercury or Venus.
 - r', b', l', the same quantities for the earth.
 - c, the angular distance of the planet and earth as seen from the center of the sun.
- ω , the position angle of the point in which the shadow-axis intersects the plane of XY, counted from the axis of X towards that of Y.

422

R', the linear radius of the sun.

R, the linear radius of the planet.

f, the semi-angle of the shadow cone.

 ρ_0 , the radius of the cone on the plane of reference.

EFFECT OF ABERRATION.

The preceding quantities require some modification in their employment owing to the motion of the planets during the interval required by light to reach them from the sun. When we compute the place of the sun from the tables for a time T, the tables are so constructed as to give its apparent direction at this moment. If τ_2 be the time required for light to reach the earth from the sun, the position we shall get from the tables for the time T will be the true one at the time $T-\tau_2$. By subtracting 180° from the longitude and changing the algebraic sign of the latitude we shall have the true direction of the earth from the sun at the moment $T-\tau_2$.

The condition that the planet, as seen from the earth, shall appear projected upon a given point of the sun's disk at a moment T', is that a ray of light, emanating from the given point at a certain moment, shall pass through the planet and through the earth, reaching the latter at the moment T'. So, putting τ_1 for the time required for the ray to reach the planet, and referring positions to the sun, the true heliocentric position of the planet at the moment $T' - \tau_2 + \tau_1$ and that of the earth at the moment T', must be in the same straight line from the given point on the sun's disk.

Therefore, in order that the positions of the earth and planet may be comparable for a moment T', we must use the true heliocentric position of the earth at this moment. This is obtained either by computing the apparent position from the tables for the moment $T' + \tau_2$, or taking the apparent position as computed for the time T', and increasing the longitude by the aberration in longitude.

The corresponding position of the planet must be the true one for the moment $T' - \tau_2 + \tau_1$. If, therefore, it is computed from the tables for the moment T' the coordinates must be corrected by subtracting the motion during the interval $\tau_2 - \tau_1$, which we may take as the interval required for the light to pass from the planet to the earth.

Value of $\tau_2 - \tau_1$. If we put

$$\tau = \tau_2 - \tau_1 = \frac{497^{\circ}.8}{3600} \ (r' - r)$$

which may be considered as the time required for light to pass from the planet to the earth expressed in hours, the required corrections to the place of the planet will be

$$\delta l = -\tau \frac{dl}{dt}$$

$$\delta b = -\tau \frac{db}{dt}$$

$$\delta r = -\tau \frac{dr}{dt}$$

the differentials being the hourly motions of the several co-ordinates of Mercury.

. In what follows these corrections will be supposed to be applied to the co-ordinates of the planet, and the corresponding ones to the positions of the earth as derived from the solar tables. That is, if we compute the tabular places of both the planet and earth for a moment T of absolute time, we must apply the preceding corrections to the heliocentric place of the planet, and add the aberration to the longitude of the earth in order that the quantities may be comparable for the moment T.

The co-ordinates x, y, and z of the center of the earth are given by the formulæ

$$x \equiv r' \sin c \cos \omega$$

 $y \equiv r' \sin c \sin \omega$

The angles c and ω are given by the equations

$$\sin c \cos \omega = \cos b' \sin (l - l')$$

$$\sin c \sin \omega = \cos b \sin b' - \sin b \cos b' \cos (l - l')$$
(1)

For these equations we may put, owing to the minuteness of b', b, and (l-l')

$$\sin c \sin \omega = \sin (b' - b)$$

 $\sin c \cos \omega = \sin (l - l')$ (1)

without an error exceeding o".o1 in a transit. Or, yet more simply, we may suppose

$$c \sin \omega = b' - b$$

$$c \cos \omega = l - l'$$
(1)"

without introducing an error of which the average value will exceed o",o1.

By these formulæ the values of x and y, for the earth's center, may be computed for any required moment. Their derivatives with respect to the time will be given with sufficient approximation by the formulæ

$$\frac{dx}{dt} = r' \left(\frac{dl}{dt} - \frac{dl'}{dt} \right)$$
$$\frac{dy}{dt} = r' \left(\frac{db'}{dt} - \frac{db}{dt} \right)$$

the effect of the change of r' being unimportant. But the quantity $\frac{db'}{dt}$ may always be regarded as insensible.

For the radius of the shadow cone on the fundamental plane we have, by the theory of eclipses,

$$\rho_0 \equiv r' \cos c \tan f \ \mathrm{R}' = \sec f$$

The value of f may be obtained by the consideration that the radius of the cone on a plane passing through the center of the sun is $-R' \sec f$, while, on a plane passing through the center of the planet, it is $\pm R \sec f$, the positive sign holding for the cone whose vertex is between the sun and planet, and the negative sign for that

whose vertex is between the earth and planet. The former is the cone of external and the latter that of internal contact. The difference of these radii is $r \tan f$, that is,

$$r \tan f = (R' \pm R) \sec f$$

or

$$\sin f = \frac{R' \pm R}{r}$$

The value of the radius ρ_0 may now be expressed in the form

$$\rho_0 \cos f = \frac{r'}{r} (R' \pm R) \cos c - R'$$

At the earth's center the condition of contact of the limb of the planet with that of the sun is

$$r' \sin c = \rho_0$$

or, dividing by r' and substituting the value of ρ_0 ,

$$\sin c = \frac{\rho_0}{r'} = \frac{\cos c}{\cos f} \left(\frac{R'}{r} \pm \frac{R}{r} - \frac{R'}{r'} \sec c \right) \tag{2}$$

The quantities c and f are so small, and vary so slightly for transits of the same planet at the same node, that their cosines may, in this formula, be supposed to have the same value for all such transits.

The moment at which the condition of geocentric contact is fulfilled may be found by Bessel's method of eclipses. We select a moment near the time of contact and compute the values of c and ω for this moment from equations (1). Let us call T_0 the moment in question, and c_0 and ω_0 the special values of c and ω thus found. Let us also compute the hourly variations of c cos ω and of c sin ω , which we call n cos ω' , and n sin ω' , from the formulæ,

$$n \sin \omega' = \frac{db'}{dt} - \frac{db}{dt}$$

$$n\cos\omega'=rac{dl}{dt}-rac{dl'}{dt}$$

Let us also put

$$\mathbf{r} = \frac{\cos c}{\cos f} \left(\frac{R'}{r} \pm \frac{R}{r} - \frac{R'}{r'} \sec c \right)$$
 (3)

and

$$\sin \psi \equiv \frac{c_0 \sin (\omega' - \omega_0)}{\mathbf{r}}$$

then

$$\tau = -\frac{c_0 \cos(\omega' - \omega_0)}{n} \mp \mathbf{r} \cos \psi \tag{4}$$

Each value of $T_0 + \tau$ will then be a time of true geocentric contact, the earlier being first, and the later second contact.

By using the two values of **r** we shall have four times of contact in all, the one

pair corresponding to external and the other to internal contact The condition to be fulfilled at each contact will be:

$$c = \mathbf{r}$$
 (5)

By what precedes we have found a moment $T + \tau$ at which this condition is fulfilled at the center of the earth. In the case of an actual observation, the observer is not at the center of the earth, but at its surface, and we have next to find the time at which he is on the surface of the shadow cone, or the reduction from contact at center to contact at his station. If, now, we suppose c_1 to represent the angular distance of the observer from the planet as seen from the sun's center, and all the other quantities which refer to the earth's center to refer to the observer, the same equations will hold true. The difference of directions between the station and the earth's center, as seen from the sun, is simply the sun's parallax in longitude and latitude. If we put ρ , β , λ the observer's distance from the earth's center, in units of the equatorial radius of the earth, and the latitude and longitude of his zenith; π the sun's equatorial horizontal parallax at the date; b'_1 , b'_1 , c'_1 , the latitude, longitude, and distance of the observer, as seen from the sun, we shall have with all necessary precision,

$$l'_{1} = l' + \rho \cos \beta \sin \pi \sin (\lambda - l')$$

$$b'_{1} = b' + \rho \sin \beta \sin \pi$$

$$r'_{1} = r' \left\{ 1 + \rho \cos \beta \sin \pi \cos (\lambda - l') \right\}$$

$$l - l'_{1} = l - l' - \rho \cos \beta \sin \pi \sin (\lambda - l')$$

$$b'_{1} - b = b' - b + \rho \sin \beta \sin \pi$$

$$r'_{1} - r' = r' \rho \cos \beta \sin \pi \cos (\lambda - l')$$
(6)

or

Substituting these values in (1)'', noting that the parallax is so small that the change in the signs of b'-b and l-l' may be taken the same as in the arcs themselves, and putting c_1 and ω_1 for the values of c and ω which refer to the station, we shall have

$$c_1 \sin \omega_1 \equiv c \sin \omega + \rho \sin \beta \sin \pi$$

$$c_1 \cos \omega_1 \equiv c \cos \omega - \rho \cos \beta \sin \pi \sin (\lambda - l')$$
(7)

From these equations the varying values of c and ω may be computed for any place at any moment. But what we really want is the time at which c_1 has the value \mathbf{r}_1 , the latter being the value of \mathbf{r} when r_1 is substituted for r in (3). By this substitution we find, to quantities of the first order

$$\mathbf{r}_{1} - \mathbf{r} = \frac{R'}{r'} \rho \cos \beta \sin \pi \cos (\lambda - l')$$

$$= \rho \sin S \cos \beta \sin \pi \cos (\lambda - l')$$

where we put S for the sun's geocentric angular semi-diameter. At the moment of geocentric contact we have $c = \mathbf{r}$, while at the required moment of local contact we must have

$$c_1 = \mathbf{r_1}$$

and the problem is to find the interval after geocentric contact when this will occur. This interval will be so small that we may regard the quantities in the equations (7) as varying uniformly through its extent. If, then, we put

$$q = + \rho \sin \beta \sin \pi$$

$$p = -\rho \cos \beta \sin \pi \sin (\lambda - l')$$
(8)

the quantities being taken for the moment of geocentric contact, the equation (7) gives, for the condition of local contact,

$$\mathbf{r}_{1} \sin \omega_{1} \equiv \mathbf{r} \sin \omega + q + \left(\frac{dq}{dt} + n \sin \omega'\right) t$$

$$\mathbf{r}_{1} \cos \omega_{1} \equiv \mathbf{r} \cos \omega + q + \left(\frac{dp}{dt} + n \cos \omega'\right) t$$
(9)

and the problem is reduced to finding the values of ω_1 and t from these equations. The first will be the local position-angle of the two bodies at the moment of local contact, and t will be the correction to reduce geocentric to local contact. The latter quantity is, in fact, the only one that is wanted, since the position-angle ω cannot be observed.

The preceding equations can, if desired, be rigorously solved for any station by Bessel's eclipse formulæ, as follows:

$$\mathbf{r}_1 = \mathbf{r} + \rho \sin S \sin \pi \cos \beta \cos (\lambda - l')$$

Find m and M from the equations:

$$m \sin M \equiv \mathbf{r} \sin \omega + q$$

 $m \cos M \equiv \mathbf{r} \cos \omega + p$ (10)

and m' and N, ψ and t, from the equations:

$$m' \sin N = n \sin \omega' + \frac{dq}{dt}$$

$$m' \cos N = n \cos \omega' + \frac{dp}{dt}$$

$$\sin \psi = \frac{m \sin (M - N)}{r_1}$$

$$t = \frac{\mathbf{r}_1 \cos \psi - m \cos (M - N)}{r_1}$$

If T is the moment of geocentric contact, T + t will be that of local contact.

In most cases, however, an approximate method leading to the usual formulæ will be sufficient. The quantities t and q are, when at their maximum, smaller than \mathbf{r} in the ratio of the radius of the earth to that of the shadow cone, or roughly in transits of Mercury, 1:150 in a May transit and 1:250 in a November transit. Also, p' and q' are smaller than n in about the same ratio. Therefore, the development in powers of these quantities will converge very rapidly.

Squaring the equations (9) and taking the sum, in order to eliminate ω' we have, omitting the second powers of the small quantities p, q, p't, q't,

$$\mathbf{r}_1^2 \equiv \mathbf{r}^2 + 2 \mathbf{r} (p \cos \omega + q \sin \omega) + 2 \mathbf{r} nt \cos (\omega - \omega')$$

or

$$\mathbf{r}_1^2 - \mathbf{r}^2 \equiv 2 \mathbf{r} \left(p \cos \omega + q \sin \omega \right) + 2 \mathbf{r} nt \cos \left(\omega - \omega' \right) \tag{11}$$

The quantity $\mathbf{r}_1^2 - \mathbf{r}^2 = (\mathbf{r}_1 + \mathbf{r}) (\mathbf{r}_1 - \mathbf{r})$ is very small. \mathbf{r}_1 may be derived from A. P., PART VI—9

the value of \mathbf{r} in (3) by substituting r_1' for r'. We thus find from the expression for r_1' in (6), neglecting the quotient of the radius of the planet divided by that of the sun,

$$\mathbf{r}_{1} - \mathbf{r} = \frac{R'}{r'} \rho \sin \pi \cos \beta \cos (\lambda - l')$$

But, $\frac{R'}{r'}$ is the sine of the sun's angular semi-diameter as seen from the earth, which we have called S. Therefore,

$$\mathbf{r}_1 - \mathbf{r} = \rho \sin S \sin \pi \cos \beta \cos (\lambda - l')$$

Thus we have, with all necessary exactness,

$$\mathbf{r}_1^2 - \mathbf{r}^2 \equiv 2 \mathbf{r} (\mathbf{r}_1 - \mathbf{r}) \equiv 2 \mathbf{r} \sin S \rho \sin \pi \cos \beta \cos (\lambda - l')$$

It is scarcely possible, from any number of observations of a transit of Mercury, to obtain the time of contact without an uncertainty of more than a second of time. The error from neglecting all the powers of $\frac{p}{r}$ and $\frac{q}{r}$ will rarely amount to a second, except when the least geocentric distance of centers is nearly as great as the sun's semi-diameter. In this case it will be more convenient to use the rigorous formulæ (10). In all other cases we may take the approximate expression (11). So substituting the above value of $\mathbf{r}_1^2 - \mathbf{r}_2$ in (11), and solving with respect to t, we find

$$t = \frac{\rho \sin S \sin \pi \cos \beta \cos (\lambda - l') - p \cos \omega - q \sin w}{n \cos (\omega - \omega')}$$

Substituting for p and q their values, this expression reduces to

$$t = \frac{\rho \sin \pi \left\{ \sin S \cos \beta \cos (\lambda - l') + \cos \omega \cos \beta \sin (\lambda - l') - \sin \omega \sin \beta \right\}}{n \cos (\omega - \omega')}$$

The quantities β and λ , which represent the latitude and longitude of the observer's geocentric zenith, are given by equations:

$$\cos \beta \cos \lambda = \cos \varphi' \cos \tau$$

$$\cos \beta \sin \lambda = \cos \varphi' \cos \varepsilon \sin \tau + \sin \varphi' \sin \varepsilon$$

$$\sin \beta = \sin \varphi' \cos \varepsilon - \cos \varphi' \sin \varepsilon \sin \tau$$

where ε is the obliquity of the ecliptic, φ' the observer's geocentric latitude and τ the local sidereal time. If we substitute these values in the expression for t, it may be expressed in the form

$$t = A\rho \sin \varphi' + B\rho \cos \varphi' \cos \tau + C\rho \cos \varphi' \sin \tau \tag{12}$$

where

$$\Lambda = \frac{\sin \pi}{n \cos (\omega - \omega')} \left\{ -\cos \varepsilon \sin \omega + \sin \varepsilon (\cos \omega \cos l' + \sin S \sin l') \right\}$$

$$B = \frac{\sin \pi}{n \cos (\omega - \omega')} \left\{ -\cos \omega \sin l' + \sin S \cos l' \right\}$$

$$C = \frac{\sin \pi}{n \cos (\omega - \omega')} \{ \sin \epsilon \sin \omega + \cos \epsilon (\cos \omega \cos l' + \sin S \sin l') \}$$

In these equations the coefficient sin S is only 0.0046; it is, therefore, of the same order of magnitude with quantities which we have neglected. It may, however, be readily taken into account by substituting for l' the quantity $l' - \sin S$ sec $\omega = l' - 16'$ sec ω , which corrected value of l' we may call l''. Developing to quantities of the first order with respect to the small quantity S, we have

$$\cos \omega \sin l'' \equiv \cos \omega \sin l' - \sin S \cos l'$$

 $\cos \omega \cos l'' \equiv \cos \omega \cos l' + \sin S \sin l'$

Making these substitutions, and putting π instead of $\sin \pi$, the values of A, B, and C will become

$$A = \frac{\pi}{n\cos(\omega - \omega')} \{ \sin \varepsilon \cos \omega \cos l'' - \cos \varepsilon \sin \omega \}$$

$$B = -\frac{\pi}{n\cos(\omega - \omega')} - \cos \omega \sin l''$$

$$C = \frac{\pi}{n\cos(\omega - \omega')} \{ \sin \varepsilon \sin \omega + \cos \varepsilon \cos \omega \cos l'' \}$$

The computations of these quantities and of the final values of t in (12) may be most readily effected as follows. From

$$p \sin P \equiv \sin \omega$$

$$p \cos P \equiv \cos \omega \cos l''$$

find p and P Then,

$$A = \frac{p\pi \sin (\varepsilon - P)}{n \cos (\omega - \omega')}.$$

From

$$k \sin K = p \cos (\varepsilon - P)$$

 $k \cos K = -\cos \omega \sin l''$

find k and K. Then,

$$D = \frac{\pi k}{n \cos(\omega - \omega')}$$

and

$$t = A\rho \sin \varphi' + D\rho \cos \varphi' \cos (K - \tau).$$

Here we may take for τ the local sidereal time of geocentric contact. If we put L, the west longitude of the place, τ_0 , the Greenwich sidereal time of contact, expressed in arc, we shall have

$$\tau = \tau_0 - L$$

$$t = A\rho \sin \varphi' + D\rho \cos \varphi' \cos (K - \tau_0 + L)$$
(13)

which is equivalent to the usual formula.

Reductions of the constants in the preceding formula to numbers.

Having a number of transits to reduce, the work will be facilitated by reducing the preceding formulæ, so far as possible, to numbers. The following are the adopted values of the semi-diameters of the sun and Mercury.

Sun:
$$R' = \sin 959''.78 = .00465316$$

Mercury: $R = \sin 3''.30 = .00001600$

In forming \mathbf{r} from (3) the cosines of the small angles c and f vary so slightly that they may be assumed to have the same values for all May transits and for all November transits. The principal quantities to be used are as follows:

			1	May transits.	November transits.
r', (approximate)			-	1.0096	0.9904
r, (approximate)		-	-	0.4516	0.3139
$\sin f$ (external contact)		-	-	0.01033	0.01487
$\sin f$ (internal contact)		•	-	0.01026	0.01477
$\sin c$ (external contact)		•	-	0.00572	0.01018
$\sin c$ (internal contact)		-	-	0.00565	0.01008
$\log \cos c \sec f(R' + R)$ (in	sec])		- 2.983678	8 2.983688
$\log \cos c \sec f(R'-R)$ (in	sec))		- 2.98069	3 2.980702
$\log R' \sec f (\text{in sec})$	-	-		- 2.98219	6 2.982220

We therefore have from (3) the following numerical formulæ for r in seconds:

May transit, external contact,
$$\mathbf{r} = \frac{[2.983678]}{r} - \frac{[2.982196]}{r'}$$

May transit, internal contact, $\mathbf{r} = \frac{[2.980693]}{r} - \frac{[2.982196]}{r'}$

November transit, ext. contact, $\mathbf{r} = \frac{[2.983688]}{r} - \frac{[2.982220]}{r'}$

November transit, int. contact, $\mathbf{r} = \frac{[2.980702]}{r} - \frac{[2.982220]}{r'}$

The following are the extreme values of the aberration time, from which intermediate values can be found as with the argument $\log r$:

May transits -
$$\begin{cases} \log r = 9.6522; \ \tau_2 - \tau_1 = 279.1 \\ \log r = 9.6580; \ \tau_2 - \tau_1 = 276.1 \end{cases}$$
November transits
$$\begin{cases} \log r = 9.4942; \ \tau_2 - \tau_1 = 337.8 \\ \log r = 9.4997; \ \tau_2 - \tau_1 = 335.6 \end{cases}$$

Taking 8".848 as the mean solar parallax, we have

For a May transit: $\log \pi = 0.9427$. For a November transit: $\log \pi = 0.9510$.

Reductions to external contact.

For reasons already given, only last external contacts have been used. Instead of computing them independently, they have been obtained from those of last internal contact by computing the difference of times of the two phases. Taking the difference between the two values of r for the two classes of contact we find them to be:

November transits:
$$\Delta r \equiv 21'' \circ 2$$
.
May transits: $\Delta r \equiv 14''.61$.

If we represent by Δ the changes of the quantities to reduce from internal to external contact, we have

$$c\Delta c = (l - l') (\Delta l - \Delta l') + (b' - b) (\Delta b' - \Delta b)$$

By substituting

$$\Delta l \equiv \frac{dl}{dt} \Delta t$$
, etc.,

we find

The condition of contact being $\Delta c = \Delta \mathbf{r}$, we have, for the values of Δt

For November transits,
$$\Delta t = \frac{21''.02}{n \cos{(\omega - \omega')}}$$

For May transits,
$$Jt = \frac{14''.61}{n \cos (\omega - \omega')}$$

These corrections are to be applied to the times of internal contact to reduce them to those of external contact.

§ 3.

Tabular heliocentric positions of Mercury and the earth.

The tabular heliocentric positions of Mercury and the earth are derived from Leverrier's tables in Vols. IV and V of his *Annales de l'Observatoire*. They are exhibited in the following table.

The first two columns give the dates and the Paris and Greenwich mean times of computation. In the second column the first number is the Paris time which was used unchanged in the computations. It was originally intended to choose this time so as to correspond to the nearest hour and sometimes the nearest simple fraction of an hour to the observed contact. But as the work was performed before the contacts were carefully examined this condition is frequently not fulfilled.

The second number of this column gives the Greenwich time corresponding to the Paris time.

The third number gives the Greenwich time as corrected for aberration, and is less than the time of computation by the interval required for light to pass from the planet to the earth.

The aberration time given in the last column is the time required for light to pass from Mercury to the earth. Along with it is given the motion of Mercury in longitude during this interval. As already stated, and as will be presently shown more fully, the longitude of Mercury is to be ultimately referred to a moment at which the ray of light, indicating contact to the observer, passed it.

The third column gives in the first line of each set the longitude of Mercury referred to the mean equinox of the date for a moment earlier than the first mean time in column two by the aberration time. The longitude was first computed for the given Paris time, and the motion in longitude during the aberration time was then subtracted. Hence, to find the longitude for the given Paris time, the correction given in the last column must be applied positively to the longitude of Mercury in the second column.

Under each longitude of Mercury is given the longitude of the earth, which is also referred to the mean equinox, for the moment first indicated in the second column. The tabular longitude of the sun is freed from the effect of aberration in order to have the longitude of the earth for the given moment.

Under each pair of longitudes is given their difference found by simple subtraction.

The latitudes of Mercury and the earth in the fifth column are given in the same way as the longitudes; that is, the latitude of Mercury is that which corresponds to the moment found by subtracting aberration time from the time of computation in the second column, and which is the third of the given times. The hourly motions in longitude and latitude are computed for each date independently by means of the differences in the tables. Hence, when two places are given for an interval of a few hours the hourly motions may be used to check the computations.

It may, however, be remarked that these hourly motions are those obtained for the original moment of computation without respect to the aberration time. Hence, to correspond strictly to the longitude, they should be reduced for aberration time. The necessary reduction is so small that no account has been taken of it.

In the column "Perturbations by Venus" are given the perturbations of Mercury and of the earth, and also their differences. Since the phenomena of contact depend entirely upon relative position, only the difference of perturbations need be considered.

The column $\log r$ gives the logarithm of the radii vectores of Mercury and the earth for the times given in the second column, uncorrected for aberration. In strictness they should be corrected for the aberration times like the longitudes and latitudes. This correction has been made in the subsequent work, but not in the tabular exhibit.

Theory of the correction for aberration when heliocentric elements are used.—The general basis of this theory has already been given. But the following more careful and rigorous examination of it may be desirable.

Let us put

$$l_0, b_0, r_0,$$

the absolute longitude, latitude, and radius vector of Mercury for a certain moment of computation from the tables, which moment we take as the zero of time:

l', b', r', the hourly variations of these quantities;

L₀, B₀, R₀, the absolute longitude, latitude, and radius vector of the earth for the same moment of time.

L', B', R', their hourly variations;

 τ_1 the time required for light to pass from the sun to the planet;

 τ_2 the time required to pass from the sun to the earth.

We shall then have, with all necessary approximation,

$$\tau_3 \equiv \tau_2 - \tau_1$$

for the time required for light to pass from the planet to the earth.

We shall then have for any time t after the moment of computation values of the absolute co-ordinates of the two bodies given by equations of the form

$$l \equiv l_0 + l't$$

 $L \equiv L_0 + L't \text{ etc., etc.}$

The phenomena of contact are determined by the condition that a ray of light leaving the limb of the sun at a certain moment shall graze the surface of the planet at a moment τ_1 later, and reach the eye of the observer yet later by the time τ_3 . Hence, if we put t_0 for the interval after the zero of time when the required ray of light left the sun, it will reach the planet at the moment $t_0 + \tau_1$, and the observer at the moment $t_0 + \tau_2$. Hence the time t_0 is to be determined by the condition that the position of some point on the planet at the moment $t_0 + \tau_1$ and of some point on the earth at the moment $t_0 + t_2$ shall be in the same straight line, or be in some definite relative position not differing much from a straight line.

The co-ordinates of the two bodies at these moments will be, For the planet,

$$l_0 + l' (t_0 + \tau_1) \beta_0 + \beta' (t_0 + \tau_1) r_0 + r' (t_0 + \tau_1)$$

And for the earth,

$$\begin{aligned} & L_0 + L' (t_0 + \tau_2) \\ & B_0 + B' (t_0 + \tau_2) \\ & R_0 + R' (t_0 + \tau_2) \end{aligned}$$

Now the condition of contact is that the position of the three bodies at the times thus indicated shall be such that the observer shall be on the cone surrounding the sun and planet. Assuming t_0 to be determined by this condition the actual moment of contact as seen by the observer will be $t_0 + \tau_2$.

If then we put

$$t_1 \equiv t_0 + \tau_2$$

If also we put

$$l_{1} \equiv l_{0} - l' (\tau_{2} - \tau_{1})$$

$$\beta_{1} \equiv \beta_{0} - \beta' (\tau_{2} - \tau_{1})$$

$$r_{1} \equiv r_{0} - r' (\tau_{2} - \tau_{1})$$

The condition of contact will be that at the time t_1 the co-ordinates determined by the equations

$$l = l_1 + l' t_1$$

$$\beta = \beta_1 + \beta' t_1$$

$$r = r_1 + r' t_1$$

$$L = L_0 + L' t_1$$

$$B = \beta_0 + B' t_1$$

$$R = R_0 + R' t_1$$

shall fulfill the required condition.

We may now describe the third and fifth columns of the table as giving the values of the quantities l_1 , L_0 , b_1 , B_0 and their differences. The quantities l, b, r, L, B, R, are now of the same general form with that assumed in § 1 of this part as the basis of the investigation. The time t_1 takes the place of t, and the co-ordinates l_1 , β_1 , etc., take the place of the co-ordinates at the zero of time. Hence, the equations of § 1 may be applied unchanged, merely taking t_1 as the unknown quantity instead of t Moreover, the time t_1 will express the local time of actual contact at the earth's surface.

The computation of the several quantities in this table were all made in duplicate, and in case where the discrepancy approximated to the tenth of a second the computations were re-examined and reconciled. Where the difference did not exceed two or three hundredths of a second, and might, therefore, be attributed to the accumulation of accidental errors in taking out numbers from the tables, the mean of the two results was adopted. The form in which the work is presented is such as to render very easy the discovery of any accidental error. The aberration time in the last coumn is equal to $\tau_1 - \tau_2$.

§ 4.

Computation of tabular times of contact and other quantities.

In order to afford the most convenient method of introducing any necessary correction, the principal numbers which occur in computing the tabular times of contact and other elements from the preceding formulæ are shown in the following table. Only those lines in which the results are completely carried out are to be regarded as definitive; the others were provisional computations made for the purpose of approximately determining the tabular times. They are inserted to make more easy the discovery of accidental errors, or the introduction of any changes in the elements.

The second column of the table gives the assumed times of computation.

Column Δt gives the computed correction to the assumed time.

Column t gives the definitive Greenwich mean times of geocentric internal contact thus obtained.

§ 5·

Symbolic corrections to the tabular relative positions of Mercury and the earth in terms of corrections to elements.

We next require the change in the time of geocentric contact produced by changes in the elements. If we first take as the co-ordinates for the position of Mercury,

- θ , the longitude of its node;
- u, its argument of latitude;
- i, the inclination of its orbit;

we shall have the following values of l and b:

$$l = 0 + u_1$$

$$\sin b = \sin i \sin u$$
where $\tan u_1 = \cos i \tan u$

Hence differentiating and substituting for $\frac{\cos^2 u_1}{\cos^2 u}$ its value, $\sec^2 b$,

$$\delta l = \delta \theta + \cos i \sec^2 b \, \delta u$$

$$\delta b = \sin i \sec b \cos u \, \delta u$$

Owing to the minuteness of the latitude during a transit, we may put sec b = 1. We then have, with sufficient approximation,

$$\delta l = \delta \theta + \cos i \, \delta u$$

$$\delta b = \sin i \cos u \, \delta u$$

We need not vary i because it cannot be corrected from transits.

From the equations (1)" of §1 we have

$$c \equiv (l - l') \cos \omega + (b' - b) \sin \omega$$
.

The earth's latitude b' may be assumed as so well known as not to need correction. So, differentiating this last equation, we have

$$\delta c = \cos \omega \, (\delta l - \delta l') - \sin \omega \, \delta b$$

Substituting for δl and δb their values just given

$$\delta c \equiv \cos \omega \, (\delta \theta - \delta l') + (\cos \omega \, \cos i - \sin \omega \, \sin i \, \cos u) \, \delta u$$

During a transit at the ascending node (a November transit) the value of u must be contained within the limits $\pm 5^{\circ}$, and during one at the descending node (a May transit) within the limits $180^{\circ} \pm 3^{\circ}$. We may therefore suppose $\cos u$ equal to + 1 during a November transit, and to - 1 during a May transit.

The preceding expression will thus become:

$$\delta c \equiv \cos \omega (\delta \theta - \delta l') + \cos (\omega + i) \delta u \text{ for November.}$$
 $\delta c \equiv \cos \omega (\delta \theta - \delta l') + \cos (\omega - i) \delta u \text{ for May.}$ (2)

We have next to express δu in terms of the corrections of such of the elements of the orbit of Mercury as admit of correction from observed transits. We shall however first transform the equations, so that the longitude in orbit shall enter instead of u, putting

v, the longitude in orbit, counted from a departure point in its moving plane. We shall then have

$$\delta u \equiv \delta v - \cos i \delta \theta$$

Substituting this value of δu in (2)

$$\delta c = \{\cos \omega - \cos i \cos (\omega + i) \} \delta \theta - \cos \omega \delta l' + \cos (\omega + i) \delta v$$

= \sin (\omega + i) \sin i \delta \theta - \cos \omega \delta l' + \cos (\omega + i) \delta v

in which i is to be taken positive in a November and negative in a May transit.

The coefficients of δv and $\delta l'$ are so nearly identical that separate values of these quantities cannot be obtained. Indeed, it is evident that, since the phenomena depend only upon the relative positions of the earth and Mercury, it is not possible to obtain the absolute position of either. We may, in fact, express the last equation in the form

$$\delta c = \sin (\omega + i) \sin i (\delta \theta - \delta l') + \cos (\omega + i) (\delta v - \cos i \delta l')$$
 (3)

Supposing the corrections $\delta\theta$, $\delta l'$, and v constant, we could, from a system of equations of this form, obtain values of the two expressions $\delta\theta - \delta l'$ and $\delta v - \cos i \delta l'$. When, from other data, the value of $\delta l'$ is found, its substitution will give the required values of $\delta\theta$ and δv .

Since observations of contact give only the time when the relative position of the bodies have a certain relation to their semi-diameters, namely, the moment at which $c - \mathbf{r} = 0$, it is necessary to include $\delta \mathbf{r}$ as well as δc in the equations. An approximate value of \mathbf{r} from the equation (3) of § 4, is, for internal contact,

$$\mathbf{r} = \frac{R' - R}{r} - \frac{R'}{r'}$$

R and R' being the angular semi-diameters of the sun and Mercury at distance unity.

We have by differentiating this expression

$$\delta \mathbf{r} = \left(\frac{1}{r} - \frac{1}{\hat{r}'}\right) \delta \mathbf{R}' - \frac{1}{r} \delta \mathbf{R},$$

or reduced to numbers

FOR A NOVEMBER TRANSIT,
$$\delta \mathbf{r} \equiv 2.18 \ \delta R' - \frac{1}{3}.19 \ \delta R$$
FOR A MAY TRANSIT,
$$\delta \mathbf{r} \equiv 1.22 \ \delta R' - 2.21 \ \delta R$$
(4)

For external contacts we have only to change the sign of δR , obtaining

$$\delta \mathbf{r} = 2.18 \, \delta \mathbf{R}' + 3.19 \, \delta \mathbf{R}$$

$$\delta \mathbf{r} = 1.22 \, \delta \mathbf{R}' + 2.21 \, \delta \mathbf{R}$$
 (5)

In the equation (3) the absolute residual is δc , or the correction to the tabular distance of centers. But, in practice, it may be more convenient to make use of times of contact. The equations (1)" give, by differentiation, and omission of the change in b', which is insensible,

$$\frac{dc}{dt} = \cos \omega \left(\frac{dl}{dt} - \frac{dl'}{dt} \right) - \sin \omega \frac{db}{dt}$$

So near the node as a transit of Mercury can be observed we may put

$$\frac{dl}{dt} = \frac{dr}{dt} \cos i$$

$$\frac{db}{dt} = \frac{dv}{dt} \sin i$$

which will give

$$\frac{dc}{dt} = \cos (\omega + i) \frac{dv}{dt} - \cos \omega \frac{dl'}{dt}$$

i being, as before, positive at the ascending node (November) and negative at the descending node (May). Since

$$\delta c = rac{dc}{dt} \, \delta t$$

the correction to the tabular time would be expressed by the equation

$$\left(\begin{array}{cc} \cos{(\omega+i)} & \frac{dv}{dt} - \cos{\omega} \frac{dl'}{dt} \end{array}\right) \delta t = \sin{(\omega+i)} \sin{i} \left(\delta \theta - \delta l'\right) \\ + \cos{(\omega+i)} \left(\delta v - \cos{i} \delta l'\right)$$

A somewhat more elegant form might be given this equation by dividing it throughout by $\cos (\omega + i)$, but since the probable errors of observations should be referred to the distance of centers rather than to the time we shall retain it in its present form.

From the tables of heliocentric positions to be given hereafter it will be seen that the values of $\frac{dv}{dt}$ for a November transit range between 901" and 925" per hour, the mean value being 913". By adopting this mean value as applicable to all the November transits we shall nearly always have the correct value of the co-efficient within one hundredth, and as the errors of Leverrier's tables can scarcely ever exceed 20 seconds, and the necessary probable error of all contact observations is an entire second or more, we may use this mean value. For the same reason we may use 441" as the value of $\frac{dv}{dt}$ for all May transits. Using also the mean values for the sun's change of longitude, and reducing the unit of time to seconds we shall have

FOR A NOVEMBER TRANSIT,

(0".253 cos
$$(\omega + i)$$
 - 0" 042 cos ω) $\delta t = \sin (\omega + i) (\delta \theta - \delta l') \sin i + \cos (\omega + i) (\delta v - \cos i \delta l')$

FOR A MAY TRANSIT,

(0".122
$$\cos (\omega - i)$$
 - 0".040 $\cos \omega$) $\delta t = \sin (\omega - i) (\delta \theta - \delta l') \sin i + \cos (\omega - i) (\delta v - \cos i \delta l')$

When, instead, of δc , we use $\delta c - \delta \mathbf{r}$, as we should, we add $\delta \mathbf{r}$ (4) and (4') to the second member of the equations, obtaining

FOR A NOVEMBER TRANSIT, INTERNAL CONTACT,

(0".253
$$\cos (\omega + i) - 0$$
".042 $\cos \omega$) $\delta t = \sin (\omega + i) (\delta \theta - \delta l') \sin i + \cos (\omega + i) (\delta v - \cos i \delta l') + 2.18 \delta R' - 3.19 \delta R$

$$(\delta \theta - \delta l') \sin i$$
(6)

A. P., PART VI-11

FOR A MAY TRANSIT, INTERNAL CONTACT,

(0".122 cos (
$$\omega - i$$
) - 0".040 cos ω) $\delta t = \sin (\omega - i) (\delta \theta - \delta l') \sin i + \cos (\omega - i) (\delta v - \cos i \delta l') + 1.22 \delta R' - 2.21 \delta R$ (7)

For external contacts we use the same equations, changing the sign of the coefficient δR .

For the value of the inclination i to be used we may take 7° o' throughout. Moreover, since $\cos i$ differs from unity by less than .01, we may suppose $\cos i$ $\delta l' = \delta l'$, as $\delta l'$ itself can never exceed 2''.

The next step in order is the substitution of the elements of the earth and Mercury and the mass of Venus for the indeterminate quantities in the second members of (6) and (7).

We put

g, the mean anomaly;
π, the longitude of the perihelion on the orbit;
e, the eccentricity;
λ, the mean longitude at any epoch;
δμ, the correction to the mass of Venus.

Then, in the case of Mercury,

$$\delta v = \delta \lambda \left\{ \begin{array}{l} 1 + 0.409 \cos g + 0.104 \cos 2g \\ + 0.027 \cos 3g + 0.007 \cos 4g \end{array} \right\}$$

$$+ \delta \pi \left\{ \begin{array}{l} -0.409 \cos g - 0.104 \cos 2g \\ -0.027 \cos 3g - 0.007 \cos 4g \end{array} \right\}$$

$$+ \delta e \left\{ \begin{array}{l} 1.97 \sin g + 0.50 \sin 2g \\ + 0.13 \sin 3g + 0.104 \sin 4g \right\}$$

$$+ \delta \mu \text{ (perturbations by Venus)}.$$

Also, for the earth,

$$\begin{array}{l} \delta l' = \delta \lambda' & \times (\mathbf{1} + 0.033 \cos g') \\ - e \delta \pi' & \times \mathbf{2} \cos g' \\ + \delta e' & \times \mathbf{2} \sin g \\ \cdot + \delta \mu & \times (\text{perturbations by Venus}). \end{array}$$

We may put, for brevity,

$$h = 0.409 \cos g + 0.104 \cos 2g + 0.027 \cos 3g + 0.007 \cos 4g$$

 $k = 1.97 \sin g + 0.50 \sin 2g + 0.13 \sin 3g + 0.04 \sin 4g$

and then find h and k from the following table, which includes all the values which g can have at the time of a transit.

		· ·
g	h	k
! .		
¦ o		
135	— O. 277	+ 0.985
136	— 0. 279	+ 0.958
137	- 0. 282	+ 0.931
138	— o. 284	+ 0.904
139	- o. 286	+ 0.877
140	— o. 288	+ 0.851
338	+ 0.465	— 1.308
339	+ 0.473	— 1. 260
340	+ 0.480	— I. 2II
341	+ 0.486	— 1. 16o
342	+ 0.492	— I. 10 7
343	+ 0.498	— 1.054
344	+ 0.503	— 0.999
345	+ 0.508	- 0.942
i		

If we also put

P₁, the periodic perturbations of the longitude of Mercury by Venus, P₂, the same for the earth,

h', k', the quantities corresponding to h and k in the sun's longitude, we shall have

$$\delta v = (\mathbf{1} + \mathbf{h}) \, \delta \lambda - \mathbf{h} \, \delta \pi + \mathbf{k} \, \delta e + \mathbf{P}_1 \, \delta \mu$$

$$\delta l' = (\mathbf{1} + \mathbf{h}') \, \delta \lambda' - \mathbf{h}' \, \delta \pi' + \mathbf{k}' \, \delta e' + \mathbf{P}_2 \, \delta \mu$$

If we also put

FOR A NOVEMBER TRANSIT,

$$n = 0^{\prime\prime}.253 \cos{(\omega + i)} - 0^{\prime\prime}.042 \cos{\omega}$$

FOR A MAY TRANSIT,

$$n = 0''.122 \cos{(\omega - i)} - 0''.040 \cos{\omega}$$

and suppose $\cos i = 1$, the general equations of condition (6) and (7) will reduce to

$$n\delta t = \sin (\omega \pm i) (\delta \theta - \delta l') \sin i$$

$$+ \cos(\omega \pm i) \{ (1+h) \delta \lambda - (1+h') \delta \lambda' - k \delta \pi + h' \pi' + k \delta e - k' \delta e' + (P_1 - P_2) \delta \mu \}$$

$$+ \begin{cases} 2.18 \\ 1.22 \end{cases} \delta R' - \begin{cases} 3.19 \\ 2.21 \end{cases} \delta R$$

If all the unknown quantities in this general equation could be independently determined from transits of Mercury, they might all appear with their secular variations in the equations of condition. But, owing to the fact that transits of Mercury can be observed only at or near two opposite points of the orbit, only certain linear functions of these corrections to the elements can be actually determined from the

observed transits. In fact, the coefficients h, k, h', and k' have each nearly the same value for all the transits occurring at the same point of the orbits. It is therefore necessary to find what linear functions of the elements the transits actually observed are best adapted to give, and to determine these functions alone, leaving the elements themselves to be subsequently determined from meridian observations. The following are the expressions of δv in terms of the corrections to the elements of Mercury at the times of the several transits. An approximate weight is assigned to each, expressing the suitability of the observations for determining the value of δv .

```

Corrections to the solar elements are to be included in each of the equations, but as their coefficients may be assumed constant for all the transits at one node, they are omitted in the above table. They are, however, included in the following mean values of $\delta v - \cos i \, \delta l'$ derived from the tables above.

In the equations we shall put

- V, the mean value of $\delta v \cos i \, \delta l'$ for the November transits;
- W, the mean value of $\delta v \cos i \, \delta l'$ for the May transits;
- V', W', the secular variations of V and W.

We then have

```
\begin{array}{l} V \; \equiv \; 1.487\delta\lambda \; - \; 0.487\delta\pi \; - \; 1.137\delta e \; - \; 1 \; 01\delta\lambda' \; + \; 1.19e'\delta\pi' \; + \; 1.58\delta e', \\ W \; \equiv \; 0.716\delta\lambda \; + \; 0.284\delta\pi \; + \; 0.896\delta e \; - \; 0 \; 97\delta\lambda' \; - \; 1.11e'\delta\pi' \; - \; 1.62\delta e', \\ V' \; \equiv \; 1.487D_t \; \delta\lambda \; - \; 0.487D_t \; \delta\pi \; - \; 1.137D_t \; \delta e \; - \; 1 \; 01D_t \; \delta\lambda' \; + \; 1.19D_t \; e'\delta\pi' \; + \; 1.58D_t \; \delta e', \\ W' \; \equiv \; 0.716D_t \; \delta\lambda \; + \; 0.284D_t \; \delta\pi \; + \; 0.896D_t \; \delta e \; - \; 0.97D_t \; \delta\lambda' \; - \; 1.11D_t \; e'\delta\pi' \; - \; 1.62D_t \; \delta e'. \end{array}
```

From these values of V and W we have the following expressions for $\delta v = \cos i \, \delta l'$ in the several transits:

NOVEMBER TRANSITS.

The rigorous course would now be, in forming the equations of condition, to transfer the small terms in $\delta\lambda$, $\delta\pi$, and δe to the second members of the equations, and retain $\delta\lambda$, $\delta\pi$, and δe in a symbolic form in the solution. But the corrections to the elements of Mercury are so small that it can hardly be practicable to determine them without an uncertainty equal to their tenth part. Their coefficients in the equations are always much less than 0.1, and it is probable that in the final values of the unknown quantities these corrections would not exceed 0.01. We may, therefore, in the solution, neglect these small terms entirely.

The semi-diameters of the two bodies are also two quantities which cannot be separately determined. If we put

$$S = \delta R' - 1.60 \delta R$$

and replace $\delta R'$ by S in the general equations (6) and (7) we shall have

2.18
$$\delta R' - 3.19 \ \delta R = 2.18 \ S + 0.31 \ \delta R$$

1.22 $\delta R' - 2.21 \ \delta R = 1.22 \ S - 0.26 \ \delta R$

 δR , the correction to the semi-diameter of Mercury at distance unity, cannot exceed a small fraction of a second, the terms in δR may therefore be regarded as insensible, and we may consider the equations as determining S alone.

Finally, we shall put, for convenience in solving the equations,

$$N = \delta\theta$$
$$M = 10 \delta\mu$$

The equations for correcting the tabular times of contact will then be:

FOR A NOVEMBER TRANSIT.

$$n\delta t = \sin (\omega + i) N + \cos (\omega + i) V + \cos (\omega + i) \frac{P}{10} M$$

$$- 2.2 S$$
(3)

FOR A MAY TRANSIT.

$$n\delta t = \sin (\omega - i) N + \cos (\omega - i) W + \cos (\omega - i) \frac{P}{10} M$$

$$= 1.2 S$$
(3)

Here δt is the difference between the observed and tabular times of internal contact. This difference gives rise to another question for consideration.

Introduction of a term depending on hypothetical variations of the earth's rotation.

In several papers published in the American Journal of Science and Arts during the past twelve years the author has called attention to the fact that the mean motion of the moon is apparently subject to certain inequalities of long period which are not accounted for by any existing theory. He therefore suggested that this apparent inequality might really be due, not to the moon's motion, but to inequalities in the axial rotation of the earth on which our astronomical reckoning of time necessarily depends. It was pointed out that this question could best be settled by observations on other rapidly moving bodies, with a view of determining whether they also show apparent inequalities which could be accounted for in the same way. Eclipses of Jupiter's satellites and transits of Mercury were especially suggested as suitable for this object.

The results of the Researches on the Motion of the Moon, published in 1878, were such as to encourage the belief that the observed inequality was really in the moon's motion. It was in fact found that the moon's mean motion for about 250 years could

be represented with approximate accuracy by the addition of a single term with a period not differing greatly from 300 years. Since it seemed quite improbable that the inequality in the earth's rotation should be periodic, the balance of probability seemed in favor of the inequality being in the moon itself. But since theory had entirely failed to show any such inequality in the moon's motion the question had still to be regarded as unsettled.

Transits of Mercury have now been observed for two centuries, and for a century and a half the times of contact may be considered as determined within a very few seconds. Taking as the standard of time the earth's axial rotation between 1750 and 1850, and assuming that the observed inequalities in the moon's mean motion are to be accounted for by actual inequalities in the earth's rotation, then our measurement of time would be in error by amounts ranging from 17 seconds in one direction to 17 seconds in the other direction between 1723 and 1881. Inequalities of this amount could not fail to be indicated by the preceding observations on the transits of Mercury.

At the same time, considering the imperfections of the older observations, these assumed inequalities are not so many times greater than the possible errors of observation as to make them evident without careful treatment. Let us then consider what method is best adapted to decide the question.

On page 266 of the Researches on the Motion of the Moon is given the errors with which the astronomical determinations of time must be supposed affected, in order that the apparent inequalities in the moon's mean motion not yet accounted for by theory may be represented.

The following table shows the amount of these errors when interpolated to the times of the several observed transits of Mercury.

Year of transit.	4	1t	Year of transit.	∆t		
1677	+	8. 33	1789		#. 18	
1690	+	29	1799	_	17	
1697	+	26	1802	_	16	
1723	+	17	1822		9	
1736	+	9	1832	_	6	
1740	+	6	1845	_	2	
1743	+	4	1848		o	
1753	_	2	1861	+	2	
1756	_	4	1868	+	10	
1769	_	12	1878	+	15	
1782	_	17	1881	+	16	
1786 j	_	18	i ,			

It is to be remarked that these times are subject to a probable uncertainty of two or three seconds, arising from the fact that Hansen's tables have not been directly compared with observations of the moon between the years 1750 and 1840. It is, however, known that the errors during this period must be small, and they have necessarily been assumed to vanish in determining the value of the hypothetical error of time.

The most natural method of making the required investigation would be to form two solutions of the equations of condition afforded by transits of Mercury, one with and the other without this hypothetical correction, and to find which solution gives the smallest residuals. But, in a case like the present, in which we must not except a striking difference in the magnitude of the residuals, the result of the solutions would not necessarily be conclusive. What we shall do, therefore, will be to assume that the values of Δt should all be multiplied by a constant factor k, and to determine from the equations of condition that value of k which best satisfies the observations.

If the hypothesis of perfect uniformity in the earth's rotation is the true one, the value of k should vanish.

If the observed inequalities in the moon's mean motion arise from the cause supposed, the value of k should come out nearly equal to unity.

If k should come out different from either zero or unity by an amount greater than its possible error it would tend to show that both causes might be in operation.

Closely associated with the value of k is another constant which it would be desirable to determine. That a tidal retardation of the earth's rotation must exist can scarcely be doubted, although no reliable estimate of its amount has yet been made. We must, therefore, suppose that our astronomical measures of time need a correction of the form cT^2 , in which T is the time reckoned from any standard epoch and c is a minute constant. If we seek to determine the possible value of c from transits of Mercury we should introduce it into the equations of condition. But it will be noticed that during the period within which transits of Mercury have been observed with any accuracy the coefficient k will be of the same general kind with c, so that k and c can not be separately determined. In fact, we shall find the values of Δt to be closely represented by the formula

$$-18^4 + 60^8 T^2$$

If, therefore, we should introduce c as an additional unknown quantity it could not be determined independently of k, but our equations would give the value only of a linear function of c and k. The relation between the two quantities is such that, supposing the true value of k to be zero, the existence of a regular tidal retardation would be indicated by a small negative value of k.

§ 7.

Numerical comparison of observed and tabular quantities, with the resulting equations of condition.

. In the first of the following tables is given the comparison of the observed and tabular times of contacts, to be subsequently used as a check upon the equations of condition. The following columns are the ones which seem to need explanation.

The third column gives the Greenwich mean times of geocentric contact derived from the observations already given in Part I. Since, however, the time itself, as determined from astronomical observations, hypothetically needs a correction — $k\Delta t$, this correction is added symbolically to the observed time to render it strictly comparable with the tabular time.

The next column gives the adopted weight of the observation, which refers, not merely to the time, but to the distance of centers. No precise formula has been applied in determining these weights because of the extremely heterogenous character of the data. As a rule, the result of five fairly accordant and satisfactory observations of internal contact is considered entitled to weight I But the weight is not proportional to the number of observations, but varies in a less degree, so that 6 is the maximum weight for any one transit. Moreover, account is taken of the skill of the observers and the general accordance and certainty of the observations.

Next we have the tabular times, the computation of which has already been given, followed by the symbolic corrections produced by corrections to the elements.

The equations of condition might now be formed directly from this comparison. But, in order to secure the greatest amount of certainty in the results, the absolute terms of the equations have been independently determined by computing the values of c-r for the concluded observed moments. The following table shows the results of the two methods of determining these terms:

Interior Contacts.

The quantities thus obtained under the heads $n\delta t$ and $c_0 - r_0$ are the absolute terms of the equation of condition which are next given. The unknown quantities which enter into these equations and the expressions for the coefficients have already been given in part in δ 5.

The method of forming the equations is as follows:

The datum supposed to be given by each time of contact derived from observation is that, at a certain moment of apparent astronomical time, the heliocentric distance of centers of the earth and Mercury was equal to the sum or difference of their semi-diameters. The requirement of the equation thence derived is that, for this same moment when reduced to absolute time, the tabular quantities, when affected by the proper symbolic corrections, shall give the same equality. We now have—

Moment of observation, in absolute time, $t_0 - k\Delta t$.

At this moment, c = r.

If we put c_0 and r_0 for the values of c and r given on page 454 we have, for the theoretical terms:

Moment of computation, in absolute time, t_0 .

At this moment—

$$c = c_0$$
 $+ \sin (\omega \pm i) \text{ N}$
 $+ \cos (\omega \pm i) (\text{V or W})$
 $+ \cos (\omega \pm i) \frac{\text{P}}{\text{IO}} \text{M}$
 $r = r_0 + 2.18 \text{ S for November}$
 $r = r_0 + 1.22 \text{ S for May}.$

To reduce the tabular value of c to the moment $c - k_0 \Delta t$ it is necessary to apply the farther correction

The quantities N, V, and W are not constants, but are subjected to a secular variation. We must therefore suppose

$$N = N_0 + N't$$

$$V = V_0 + V't$$

$$W = W_0 + W't$$

t being the time from an arbitrary mean epoch.

The equation c - r = 0 now becomes,

o = sin (
$$\omega + i$$
) (N₀ + N't)
+ cos ($\omega + i$) (V₀ + V't)
+ cos ($\omega + i$) $\frac{P}{10}$ M
- 2.18 S - $nk\Delta t$
+ $c_0 - r_0$
FOR MAY,
o = sin ($\omega - i$) (N₀ + N't)
+ cos ($\omega - i$) (W₀ + W't)
+ cos ($\omega - i$) $\frac{P}{10}$ M
- 1.22 S - $nk\Delta t$
+ $c_0 - r_0$

The following explanations on special points are, however, necessary:

Exterior contacts.—In combining exterior contacts with interior ones, it is necessary to avoid as far as possible the introduction of any possible systematic error arising from the different methods of observing the two classes of phenomena. Such conditions may be expected to arise from the fact that the external tangency of the limbs cannot be really observed. The time noted by the observer is that at which the notch made by Mercury in the sun's limb became so small that he could no longer see it. This magnitude is an unknown quantity, to be determined from the observations, and the functions of the semi-diameters which enter into the expression for external contact must be considered as entirely independent of that for internal contact.

Again, the magnitude of the notch when the observer loses sight of it will depend upon the optical power of his telescope and the condition of the atmosphere. Now the optical power of the telescope has gradually improved from the time of observation of the first transit until the present. The magnitude of the last visible notch must therefore be considered as subject to a gradual variation during the period of observations of the transit. We may without danger of serious error suppose this change to have been proportional to the time. The function of the semi-diameters which enters

into the equations must therefore be supposed affected by a secular variation. Since the time of observation depends upon the optical power of the telescope, which varies with different observers, the question arises whether we are to apply corrections depending on the telescope. This is impracticable in the greater number of cases from want of the necessary data. Variations arising from differences of telescopic power must therefore be regarded as merged with the accidental errors. The question how far the accidental errors of observation will thus be increased is a serious one, to be settled only by a comparison of results.

It is an observed fact that if we reject those observations in which the telescopic power was insufficient, or in which the observer evidently could not have seen the smallest visible notch, it is found that the discordance among the observations of external contact are not enormously greater than among those of internal contact. Now, as it cannot be supposed that the observations at one transit are made with instruments systematically different from those at another transit, the result is that the probable error arising from differences of telescopic power cannot be regarded as many times greater than the regular errors of internal contact.

It is however proper to remark that the weights assigned to the observations of internal contacts in this discussion have been below rather than above that to which the author would consider them fairly entitled.

It may be questioned whether there may not be a similar progression in the observations of internal contact arising from differences of telescopic power. That such a systematic change could be found among an infinity of observations cannot be doubted. But the observations actually made do not seem to afford any sufficient data for its investigation. As a general rule, there appears to be no marked difference between observations at the same transit made with instruments of different powers. The same thing may therefore be supposed true of the earlier and later observations of transits. The fact that eleven unknown quantities are already introduced into the equations of condition affords another reason for laying the discussion of this question aside.

But there are two cases in which a difference of this kind is evident, the one the transit of 1677, the other that of 1756. The time of duration observed by HALLEY seems to indicate that his observed time of ingress was too late, and that of egress too early, a circumstance which we may attribute to deficiency of optical power. This difference is so much more striking than in the case of the following transits that the equations of condition given by HALLEY's observations have been combined into one in such a way as to eliminate the semi-diameter.

The observations of 1756, which are also exceptional from the same apparent cause, have been rejected entirely.

Owing to the small weight assigned to the observations of external contact, it has not been deemed necessary to form separate equations for them. The coefficients of the unknown quantities have therefore been assumed to be the same as those corresponding to internal contact.

If the errors of Leverrier's tables were of considerable magnitude this course would not be advisable, but since they must be regarded as almost vanishing quanti-

ties it does not appear that any serious error will result from using the same coefficients in the two cases. In fact, the preceding identity of coefficients supposes merely that the tabular interval between external and internal contact is absolutely correct, a function of the semi-diameter alone excepted.

Two modifications have been made in the equations as thus derived.

I. It was long a subject of embarrassment what to do with Halley's observations on the transit of 1677. As already remarked, the two phases are discordant by more than a minute. To express the result in another form the semi-diameter of the sun, as it would result from his observations, is some 3".5 less than its true value. After much consideration the conclusion was finally reached that this discordance was due not so much to an error in time as to a personality in Halley's method of observing the contact. Accepting this hypothesis the mean result of his observations of ingress and egress would be correct. The difference of the equations resulting from his two observations was therefore taken as entitled to a small weight, and the semi-diameter was thus eliminated from the result.

II. In assigning the relative weights given in the preceding section no account was taken of the fact that Mercury is nearer the earth in a May transit than in a November one. An error of 1" in the heliocentric place would, in November, cause an error of 0".46 in the geocentric place, and in May an error of 0".80. Hence the heliocentric place can be determined with more accuracy by a May observation than by a November one. The weights of the May transits, as given in Part I, were therefore all multiplied by 2.

III. In discussing the observations the question what to do with the second contacts observed in 1740 and 1786 was laid aside. These observations were, therefore, omitted with the view of seeing how they would be represented by the concluded theory. It would seem from this that internal contact must have actually passed some time before the moment at which Wintheop noted it as not having occurred, and, therefore, that his observation is affected with some undiscoverable error. It would also appear that the second hypothesis respecting the internal contact of 1786 is the one to be accepted, but it was not thought worth while to re-solve the equations of condition.

The observations of 1756 have been entirely dropped, as the weight to which they could be considered entitled is too small to have any influence on the result.

Equations of Condition.

k = + 0.295				± 0.065	

The solution has been so conducted as to give separate results on two distinct hypotheses:

- I. That the rotation of the earth is really uniform, and, therefore, that the true value of k is zero, and that this quantity is to be omitted from the equations.
- II. That k has a certain definite value to be derived from the equations themselves.

 On the first supposition there will be ten unknown quantities, and on the second

On the first supposition there will be ten unknown quantities, and on the second eleven.

The required result has been reached by solving the equations so as to express each of the other ten quantities in terms of k. The result of omitting k is then obtained by putting k equal to zero in these results, as above given.

The solution was then continued so as to obtain the most probable value of k itself. The weights were then obtained separately on the two hypotheses, and, irrespective of the probable errors, should be a little larger for the less number of unknown quantities. On the other hand, the probable error by supposing k to have the value of 0.295 is decidedly less, because the residuals are smaller. Hence, on the whole, the probable errors are less when we assign to k the value given by the equations than when we suppose it to vanish.

The epoch for the variable quantities N, V, W, and S_1 is 1820. For any other year Y, we have

$$W = W_0 + W' \frac{Y - 1820}{100}$$

$$V = V_0 + V' \frac{Y - 1820}{100}$$

$$N = N_0 + N' \frac{Y - 1820}{100}$$

PART III.

DISCUSSION OF RESULTS.

Of results to be derived from transits of Mercury, there are two which outweigh all others in importance: One is the possible variation of the sidereal day, which has been already described, and the other the discordance between the theoretical and the observed motions of the perihelion of Mercury. The two questions thus arising have to be considered separately, and it will be convenient to take up first the question of the variability of the earth's axial rotation.

≬ 1.

Do the transits of Mercury prove or disprove the hypothesis of the variability of the earth's axial rotation?

We have made this question depend upon the value of the constant k, deduced in the preceding sections. The evidence that we have hitherto obtained of the supposed variability is found in the discordance between the observed and theoretical mean motions of the moon. As already explained, we have so arranged the equations of condition that the hypothesis of perfect uniformity in the earth's rotation will be represented by $k \equiv 0$, and that of such variability in the rotation as will account for the inequalities of the motion of the moon by $k \equiv 1$. A value of k differing from either 0 or 1 must either arise from the unavoidable errors of observation or from a combination of both hypotheses.

As a matter of fact we have found k = + 0.295. This result does not correspond to either hypothesis.

To facilitate the judgment how far we are to consider this value of k as indicating a general change in the earth's rotation, we present the following values of the residuals corresponding to the several cases, $k \equiv 0$, $k \equiv 0$ 295, and $k \equiv +1$. The residuals are presented in two forms—those of heliocentric arc between the positions of Mercury and the earth and those of times of contact.

We begin with the former, and express them as functions of k, so that those for k = 0, k = 0.295, and k = 1 can be readily formed. We thus find the following values:

Residuals of Equations of Condition in terms of k.

We thus derive, by direct computation,

Hence, for

$$\Sigma W_{\bullet}^{2} = 109.4 - 136.4k + 237.8k^{2}$$

while the result from the solution of the normal equations is

$$\Sigma W_{\epsilon}^{2} = 109.5 - 137.2k + 232.8k^{2}.$$

$$k = 0; \quad \Sigma W_{\epsilon}^{2} = 109.4$$

$$k = 0.295; \quad \Sigma W_{\epsilon}^{2} = 89.9$$

$$k = 1; \quad \Sigma W_{\epsilon}^{2} = 210.8$$

Since what we are now aiming at is the determination of a hypothetical error of the astronomical time, a conclusion will be facilitated by presenting the mean error of time for each transit. We remark that, continuing the notation already employed, to the residual Δc in arc will correspond the residual $\Delta t = n\Delta c$ in time. Hence, to a weight W of Δc will correspond a weight proportional to Wn^2 of Δt . Hence we shall have, as the mean by weights of any number of results:

$$\Delta t = \frac{\sum \mathbf{W} \mathbf{n} \Delta c}{\sum \mathbf{W} \mathbf{n}^2}.$$

We thus have the following results from the one, two, or three contacts observed at each transit. The probable error corresponding to the unit of weight is assumed to be 1.5.

If we are compelled to choose between the two limiting values of k0, and unity the value zero is far the more probable. The probable error of k being the probability that the true value of k can be as great as 0.8 is only . This would be the probability if no systematic errors entered into the observations. But the possibility of systematic differences between observations of different transits is such that we should regard this probable error as quite illusory. Still it must be admitted that the probability that k can be nearly unity is so small that we must regard it as quite improbable that the inequalities in the mean motion of the moon are entirely to be

accounted for by changes in the earth's rotation. One of the conclusions of the present discussion is therefore this:

Inequalities in the motion of the moon not accounted for by the theory of gravitation really exist, and exist in such a way that the mean motion of the moon between 1800 and 1875 was really less than it was between 1720 and 1800.

If on the other hand we adopt the hypothesis k = 0, the systematic character of the residuals is such that this hypothesis must also appear quite improbable though not wholly impossible. The question then arises, can we admit the actual existence of inequalities of both classes? The most remarkable circumstance in this connection is that a value of k equal to about $\frac{1}{3}$ should so closely satisfy the whole series of observations. That there could be any such relation between variations in the earth's rotation and in the moon's mean motion as would be implied by supposing this value of k to be real would be a result which cannot be accounted for by known physical laws. But it is a singular circumstance that the whole series of observed transits through two centuries should so closely follow this law. It is also singular that the changes during the last 40 years should be so closely represented. It is to be remarked that the apparent retardation of the moon's mean motion during the present century has not been uniform, but that during a few years preceding 1860 there was a temporary acceleration which continued until perhaps 1862. A rapid retardation then commenced, which has gradually brought the moon back into its regular position as given by the hypothetical inequalities of long period. Now it is most remarkable that the observations of transits of Mercury agree with those of the moon, and those of the first satellite of Jupiter, in indicating that this apparent inequality was in part at least due to the earth's rotation. If we should accept this result it would lead to the conclusion that the motions of the earth and moon are so connected that one is retarded when the other is accelerated. But, it is difficult to see how such a conection could result from the mutual action of the two bodies. If these motions were connected in a way which could be accounted for by the action of a couple of forces between the two bodies they would be accelerated and retarded together. This relation would be indicated by a negative value of k.

On the whole it would seem premature to reach any positive conclusion upon these results, though they seem to suggest the desirableness of further physical investigation to ascertain the possibility of any such relation

At present the best course would seem to be to suppose $k \equiv 0$ in our subsequent investigations. The effect of k is so small that our general conclusions respecting the motion of Mercury will not be materially altered should it subsequently be found to have a value different from zero. By constructing theories and tables on the simpler hypothesis, the existence of any real deviation will be made more evident by the results of future transits.

§ 2.

Concluded corrections to Leverrier's elements.

Since we cannot derive separate and independent values of all the elements from observations of transits, the corrections which we obtain must be regarded as those

applicable to certain functions of the elements, as shown in Chap. II, § 5. Transferring the epoch from 1820 to 1850, and putting k = 0, we have the following values of the corrections to the tabular quantities. T is here the time after 1850.0, the unit being a century.

$$N = (\delta\theta - \delta l') \sin i = -0''.07 + 0''.28T$$

$$V = 1.487\delta\lambda - 0.487\delta\pi - 1.137\delta e$$

$$- 1.01\delta\lambda' + 1.19e'\delta\pi' + 1.58\delta e' = -1''.69 - 2''.63T$$

$$W = 0.716\delta\lambda + 0.284\delta\pi + 0.896\delta e$$

$$- 0.97\delta\lambda' - 1.11e'\delta\pi' - 1.62\delta e' = +1''.39 + 1''.84T$$

$$M = + 0.15$$

Hence, the mass of Venus derived from the periodic perturbations at the times of transits is

$$\frac{1.015}{401847} = \frac{1}{396000}$$

For the corrections of semi-diameters we have

$$S = \delta R' - 1.60\delta R = -0''.04$$

Hence, for the sun's semi-diameter at distance unity we have

959".75 — 1.60
$$\delta R$$

 δR being the correction to the semi-diameter of Mercury at distance unity. The value of S_1

$$-o''.50 + o''.46T$$

expresses the extent to which Mercury impinged upon the sun at the time of an average external contact. The term o".46T represents the diminution of this quantity in consequence of the gradual improvement of the telescope.

Comparison of observed and theoretical secular variations and of results for the mass of Venus.

The observed secular variation of the perihelion of Mercury, as derived from observation, can, without difficulty, be accounted for by suitably increasing the adopted mass of Venus. The only argument against such an increase is that the variations of other elements will not then be represented. But in the absence of any reason for preferring one determination to another, the true form in which we should put the result is that the variations of different elements give different values of the mass of Venus. We can reject one result only when we have found that all the methods but one give accordant results and that this one alone is discordant. The first step toward a satisfactory solution of the question is, therefore, to find what values of the mass of Venus are given by different data and discuss the discordances among them.

Five methods are available for the determination of the mass of Venus.

- I. The secular motion of the perihelion of Mercury.—More exactly we should say the secular motions of V and W, which arise from variations both in the eccentricities and in the perihelion of Mercury and the earth.
- II. The secular motion of the node of Mercury.—Any uncertainty that may exist in the theoretical motion of this node arises almost entirely from the uncertainty in the mass of Venus, since the influence of all the other planets can be accurately determined.
- III. The secular motion of the node of Venus on the ecliptic.—Properly speaking we should say the secular motion of the ecliptic itself, because that portion of the motion of the node of Venus which depends on the mass of that planet arises solely from the motion of the ecliptic.
- IV. The secular diminution of the obliquity of the ecliptic.—This, like the first, is a motion of the ecliptic due to the action of Venus. Hence these two determinations cannot be considered as wholly independent, though each would strengthen the other.
- V. The periodic perturbations of Mercury and the earth produced by the action of Venus.

Since a discordance of the kind in question indicates the continuous action of some unknown cause, we cannot say that any one of the first four methods is necessarily free from the effects of such action. Hence, if the results are discordant, we have no right to deduce with certainty any mass of Venus from them. It is different with the last method. It is beyond all moral probability that any unknown cause should produce periodic inequalities in the planetary motions corresponding to those produced by the action of the planets on each other. We may therefore consider the mass of Venus derived from periodic perturbations to be that which is to be accepted as the real mass to be used in comparing the other results. Unfortunately, the best mass that can be derived from transits is very uncertain, while that of discussing the meridian observations will be very laborious.

Mass of Venus from the motion of the perihelion of Mercury.

I. To determine what mass of Venus will best represent the secular variations of the eccentricity and perihelion, let us consider the values of V' and W', which depend upon the corrections to the secular variations. If we put

$$\delta H_1 = 0.487 \delta \pi + 1.137 \delta e - 1.19 e' \delta \pi' - 1.58 \delta e'
\delta H_2 = 0.284 \delta \pi + 0.896 \delta e - 1.11 e' \delta \pi' - 1.62 \delta e'$$
(a)

The values of V' and W', which we have found, give the equations—

1.487
$$\delta n - 1.01\delta n' - \frac{d\delta H_1}{dt} = -2''.63$$
 (b)
0.716 $\delta n - 0.97\delta n' + \frac{d\delta H_2}{dt} = +1''.84$

Where δn and $\delta n'$ are the corrections to the centennial mean motions of Mercury and the earth, respectively. There being four unknown quantities in these two equations, we cannot determine them all from the data afforded by the transits. We shall

A. P., PART VI-14

therefore take the tabular mean motion of the sun as correct, which amounts to supposing $\delta n' = 0$, and express $\frac{dH_1}{dt}$ and $\frac{dH_2}{dt}$ in terms of the mass of Venus as the single unknown quantity in addition to δn

The following values of the secular variations of π , e, π' and e' are given by LE-VERRIER,* and will be accepted with the single change of substituting, for the action of Venus, the value found by Mr. Hill by Gauss's method. (Ante, p. 342.)

$$\begin{aligned} D_{t}\pi &= 527''.00 &+ 280''.51\nu' &+ 83''.64\nu'' + 2''.85\nu''' \\ &+ 152''.59\nu^{iv} + 7''.25\nu^{v} &+ 0''.14\nu^{vi} + 0''.06\nu^{vii} \end{aligned}$$

$$D_{t}e &= + 4''.18 &+ 2''.82\nu' &+ 1''.06\nu'' &- 0''.07\nu''' \\ &+ 0''.32\nu^{iv} &+ 0''.05\nu^{v} \end{aligned}$$

$$e'D\pi' &= + 19''.30 - 0''.46\nu &+ 5.89\nu' &+ 1.89\nu''' &+ 11''.66\nu^{iv} + 0.31\nu^{v} \\ D_{t}e' &= - 8''.95 &- 0''.29\nu &+ 1''.36\nu' &- 1''.82\nu''' &- 8''.16\nu^{iv} - 0''.04\nu^{v} \end{aligned}$$

The coefficients ν , ν' , etc., are determined by the condition that $1 + \nu$, $1 + \nu'$, etc., are the factors by which we must multiply the provisional masses adopted by Leverrier to obtain the true masses. Since the time when Leverrier wrote the masses of most of the planets have been determined with a certainty far exceeding any then attainable. The following seem at present to be the most reliable values of the planetary masses:

Mercury.—Von Asten's investigations on Encke's comet indicate a large diminution of the mass of Mercury generally assumed. The different results for this mass are so discordant that the choice among them must be a matter of judgment rather than of calculation. Analogy would lead us to suppose that the density of this planet is probably less than that of the earth. It is the opinion of the writer, from a consideration of all the data, that we may adopt the value

Mass of Mercury
$$=\frac{1}{7500000}$$

as being at present the most probable value.

The Earth—The most recent determinations of the solar parallax appear to group themselves around the value 8".91, which we may regard as the most probable value now obtainable. To this corresponds

Combined mass of the Earth and Moon $=\frac{1}{327000}$

Mass of Mars.—Professor Hall's discussion, from the motions of the satellites, gives

Mass of Mars=
$$\frac{1}{3093500}$$

which does not seem to need any further discussion or correction.

Mass of Jupiter.—There does not seem to be any reason for changing Bessel's mass, which we shall therefore adopt.

^{*} Aunales de l'Observatoire, tome ii, p. 100.

Saturn, Uranus, and Neptune.—The action of these planets on Mercury and the earth is so small that there is no need of changing the masses employed by LEVERRIER.

We now have the following comparison of the masses here adopted with those adopted by Leverrier, with the resulting values of the coefficients ν .

Planet.	Mass adopted by LEVERRIER.	Corrected mass.	Value of ν.
Mercury	3,000,000	7,500,000	— o. 6
'Venus	1 401,847	Indeterm.	Unknown.
Earth	1 354,936	<u>1</u> 327,000	+ 0.0854
Mars	2,680,337	1 3,093,500	_ o. 134
Jupiter	1050	1 1047.88	+ 0.00202

Substituting these values of ν , ν'' , etc., the preceding expressions for the secular variations in terms of the mass of Venus become

In Leverrier's tables of Mercury and the sun the adopted secular variations, assuming the precession for 1850 to be 50".2357, are

$$D_{t}\pi = 567.81$$
 $D_{t}e = 4.20$
 $e'D_{t}\pi' = 19.23$
 $D_{t}e' = -8.76$

The corrections to the tabular secular variations are therefore expressed in the form

Substituting these values in the derivatives (a) of δH_1 and δH_2 with respect to the time, we have the following expressions for the theoretical corrections to the tabular secular variations of H_1 and H_2

$$D_t \delta H_1 = -16.81 + 130.6 \nu'$$

 $D_t \delta H_2 = -9.98 + 73.4 \nu'$

Substituting these theoretical expressions in the formulæ (b), and putting $\delta n' = o$, the equations derived from observation become

$$1.487\delta n + 16.81 - 130.6\nu' = -2.63$$

 $0.716\delta n - 9.98 + 73.4\nu' = +1.84$

The solution of these equations gives

$$\delta n = + 0.58$$
 $v' = + 0.1554$

This value of ν' gives

Mass of Venus =
$$\frac{1}{347800}$$

II. Motion of the node of Mercury.—Our next inquiry is, what mass of Venus results from the observed motion of the node of Mercury upon the ecliptic? If we put, with LEVERBIER,

$$p \equiv \tan i \sin \theta,$$

 $q \equiv \tan i \cos \theta,$

we have the following theoretical values of the secular variations of the planes of the orbit, derived and expressed as in the case of the perihelion of Mercury.

FOR MERCURY

$$D_{t}p = -53.69 - 27.71\nu' - 8.76\nu'' - 0.21\nu''' - 16.08\nu^{tv}$$

$$D_{t}q = +24.65 + 7.06\nu' + 7.32\nu'' + 0.17\nu''' + 9.75\nu^{tv}$$

FOR THE EARTH.

$$D_{t}p'' = + 5.89 + 0.62\nu + 7.57\nu' + 0.73\nu''' - 2.50\nu^{iv}$$

$$D_{t}q'' = - 47.59 - 0.52\nu - 28.90\nu' - 0.83\nu''' - 16.01\nu^{iv}$$

FOR MERCURY RELATIVE TO EARTH.

$$\begin{array}{l} D_{i}(p-p'') = -59.58 - 0.62\nu - 35.28\nu' - 8.76\nu'' - 0.94\nu''' - 13.58\nu^{iv} \\ D_{i}(q-q'') = +72.24 + 0.52\nu + 35.97\nu' + 7.32\nu'' + 1.00\nu''' + 25.76\nu^{iv} \end{array}$$

Substituting the values of ν , ν'' , ν''' , and ν^{iv} , already given, these last equations become

$$D_{t}(p - p'') = -59.86 - 35.28\nu'$$

$$D_{t}(q - q'') = +72.48 + 35.97\nu'$$

The secular motion of the inclination and node of Mercury relative to the moving ecliptic is found by substituting p-p'' and q-q'' for p and q in the expressions for the latter quantities and then differentiating. We thus find

$$\sin i D_t \mathcal{I} \equiv \cos i \cos \theta D_t (p - p'') - \cos i \sin \theta D_t (q - q'')$$

For the epoch 1850 we have

$$i = 7$$
 0 7.7 $\theta = 46$ 33 8.8

whence

$$\sin i D_t \theta = -93''.09 - 50''.00\nu'$$

The observed value of this same quantity is found by applying to Leverrier's tabular value the corrections already derived. We thus have

Observed
$$\sin i D_t \theta = -92''.56 + 0''.28 = -92''.28$$

Equating the values we find

$$v' = -.016$$

Hence for the mass of Venus derived from the motion of the node of Mercury, we have

$$m' = \frac{1}{408400}$$

III. Motion of the node of Venus.—The most recent determination of the motion of the node of Venus, and of the consequent mass of that planet, is that of Mr. G. W. Hill, who finds

Annual motion of node
$$=$$
 32.515 — precession $=$ $-$ 17.737

Mass of Venus* =
$$\frac{I}{427240}$$

The motion adopted in Leverrier's tables of Venus (Annales de l'Obs., vol. vi) corresponds to a yet smaller mass of Venus not far from $\frac{1}{450000}$, so that there is, apparently, an extraordinary discrepancy between the mass of Venus derived from this source and from the others. But the observations of the transit of Venus in 1874 showed that Leverrier's position of the node needed a correction about twice that found by Mr. Hill. From this it would seem probable that the geocentric latitude of Venus derived from the transits of 1761 and 1769 was several seconds in error. It must, therefore, be deemed probable that the actual motion of the node corresponds to a mass of Venus decidedly greater than that found by Mr. Hill, and not differing greatly from that found by the motion of the node of Mercury. But in the absence of a definitive investigation of the subject, no value of the mass in question can at present be derived from this source.

IV. Obliquity of the ecliptic.—The secular diminution of the obliquity of the ecliptic, as found from observation by Leverrier, indicates a diminution of the provisional

^{*} Tables of Venus, Introduction, p. 36.

mass of Venus. But this is another constant of which a definitive value is yet to be investigated, and no certain result can be laid down until this is done.

V. Results of periodic perturbations.—We have found from the equations of condition

$$M = 10v' = +0.15 - 0.43k \pm 0.13$$

The large value of the coefficient of k shows that the concluded mass of Venus from the periodic perturbations will be materially affected by any inequalities in the earth's rotation. We can, therefore, only attribute small weight to the result, which is

Should the true value of k be that given by the equations, the denominator would be increased to 401 000.

§ 4.

Concluded mass of Venus and excess of motion of perihelion of Mercury.

We have now the following results for the mass of Venus:

From perihelion of Mercury $1 \div 1000m' = 347.8$ From node of Mercury - - - - 4084 From periodic inequalities - - - - 396.

while the results from the other two sources will probably not differ much from the second of the above values.

The third value is too uncertain to permit of any conclusion being drawn from its deviation from the second. By merely supposing the constant k to have the value 0.295 not only will the last value be increased to 401, but the value 408.4 from the motion of the node will be diminished. The two values will, therefore, be made more accordant.

There is, therefore, a decided preponderance of evidence that the true value of the mass of Venus does not differ much from $\frac{I}{405\,000}$, and is probably contained between the limits $\frac{I}{400\,000}$ and $\frac{I}{410\,000}$. The value $\frac{I}{347\,800}$ is entirely inconsistent with all the others. We must, therefore, conclude that the discordance between the observed and theoretical motions of the perihelion of Mercury, first pointed out by Leverier, really exists, and is indeed larger than he supposed.

Determination of excess of motion of perihelion.—In investigating the actual amount of the discordance we call to mind that we have no certain evidence as to how the discordance is to be divided among the several elements which enter into the expressions for V' and W'. But, so far as has yet been noticed, it does not appear that any other element than the perihelion of Mercury is affected by this abnormal variation. We, therefore, put the inquiry into this form: assuming that the variations of e, e', and π'

correspond to theory, how much is the variation of π in excess of the value given by theory? In considering this question we shall assume $\nu' = -.008$ and hence $m' = \frac{1}{405000}$. We shall also put,

p, the excess in the centennial motion of π .

With this adopted value of the mass of Venus the motions of the elements which are to be reconciled with observation will become

$$D_{t}\pi \equiv 531.83 - p$$
 $D_{t}e \equiv 4.26$
 $e'D_{t}\pi' \equiv 19.30$
 $D_{t}e' \equiv -8.56$

The excess of the values adopted in the tables over these values are

$$\Delta D_t \pi \equiv 35.98 - \pi'$$

$$\Delta D_t e \equiv -0.06$$

$$\Delta e' D_t \pi' \equiv -0.07$$

$$\Delta D_t e' \equiv -0.20$$

We thence derive from the equations (a) the following values of the excess of the tabular values of D_tH_1 and D_tH_2 over the modified theory

$$\Delta D_t H_1 \doteq 17.85 - 0.487 p$$
 $\Delta D_t H_2 = 10.57 - 0.284 p$

Next, the equations (b) give for the excess of observation over the tables

$$\delta D_t H_1 = + 2.63 + 1487 \delta n$$

 $\delta D_t H_2 = + 1.84 - 0.716 \delta n$

the terms in $\delta n'$ being omitted as before.

Hence, the excesses of observation over theory, which is to be reduced to zero by attributing suitable values to p and δn , are

$$20.48 - 0.487p + 1.487\delta n$$

 $12.41 - 0.284p - 0.716\delta n$

Equating these expressions to zero we find

$$\delta n = + 0.37$$

$$p = + 42.95$$

It follows that the observed centennial motion of the perihelion of Mercury is greater by 43" than the theoretical motion computed from the best attainable values of the masses of the planets.

Speculation on possible causes of the excess of motion of the perihelion of Mercury.

Should physicists succeed in discovering some modification of the law of attraction between different bodies, which would closely represent the phenomenon in question, further investigation of the subject from an astronomical standpoint would be greatly limited. But, in the absence of any such modification, no satisfactory conclusion can be reached without more certain data than we now possess as to the exact character of the excess of motion of the perihelion of Mercury, and of the other phe nomena which may be associated with it. It is therefore difficult, in discussing the possible cause of such a motion, to speak with the confidence of certainty on every point that may come up. What we have to say must be to a considerable extent pro visional, and must be founded on the supposition that the character of the phenomena with which we are concerned is that which appears most probable from the preceding discussion.

Of course the first thing to be sure of before basing any theory upon the observed discordance is, that the latter does not arise from any imperfection either in the theory or in the discussion of the observations. The close agreement of the secular variations produced by Venus, as computed by Mr. Hill in the preceding paper of this series, and as computed by Leverrier, seem to prove conclusively the correctness of the latter's results. For any other planet than Venus the uncertainty must be much smaller. We cannot, therefore, look with any probability for an error in the computed secular variations. The question may, however, be raised, whether there is a possibility of any term of very long period. This question also must, it would seem, be answered in the negative. Any term having a period of a number of centuries would depend upon multiples of the mean motion so high that there is no possibility of their being sensible.

To show this let us develop the ratio of the mean motions of Venus and Mercury as a continued fraction. It will be—

$$\frac{\frac{1}{2}}{1} + \frac{1}{1} + \frac{1}{1} + \frac{1}{7} + \frac{1}{\text{etc.}}$$
be

The convergents will be

$$\frac{1}{2}$$
, $\frac{1}{3}$, $\frac{2}{5}$, $\frac{9}{23}$, $\frac{65}{166}$

The period of the term 23 V — 9 M will be little more than 50 years. The term 166 V — 65 M could not be sensible in the motion of the perihelion.

The most simple hypothesis is the well-known one of Leverrier, which presupposes the existence of a planet or group of planets between Mercury and the sun. That any such body or bodies of sufficient mass to produce the motion in question can really exist seems to be out of the question, for a number of reasons.

In the first place, on any probable hypothesis of the relation of mass to reflecting power, it is impossible that a planet or group of planets of sufficient mass to produce the observed motion of the perihelion of Mercury could exist without being very conspicuous objects during total eclipses of the sun, if at no other time. We cannot, indeed, assign an exact value to the mass unless we know the mean distance. But the less we suppose the mean distance, and therefore the greater we suppose the liability that the planet should be lost in the sun's rays, the greater the mass required and the more brilliant the planet or planets would shine during a total eclipse. In fact the more distant from the sun the required planet, the less readily it would be detected during an eclipse; but, on the other hand, it would be more readily detected at other times. In a paper published in Gould's Astronomical Journal, volume vi, the writer showed that if a group of sufficient magnitude existed, the transits over the sun would be too frequent to escape detection.

In the next place, no such group could exist and produce the observed effect without also disturbing the secular motions of the node of Mercury and Venus. It was shown in the paper just referred to that, supposing the group to lie in the ecliptic, the excess of motion of the node would be as great as that of the perihelion. But observations do not indicate any such excess. If, therefore, the group exists its plane must be very nearly coincident with the orbit of Mercury. But here we meet with two difficulties:

If the mean plane of the group were at any epoch coincident with that of Mercury, it could not remain so permanently, but the planes of the different orbits would, in time, group themselves near the invariable plane of the planetary system. Again, if the coincidence had place with the orbit of Mercury it could not have place with reference to the plane of Venus, and the plane of motion of that planet would be subject to a secular variation.

Now it is quite true, as already pointed out, that these several secular motions of the planes have not been investigated with such thoroughness that we can speak positively on this question. At the same time it appears extremely improbable that any disturbing action can exist of such magnitude as the hypothesis would imply.

The hypotheses just considered are those of a single planet or a group of planets. It may be asked to what limit we must suppose the subdivision carried in order that the individual bodies may escape detection. The reply is that they must be so small as to be invisible either in transit across the sun or by reflected light during a total eclipse, or in the evening after sunset. Their diameters at the distance unity cannot, therefore, exceed a very small fraction of a second.

The limit of mean diameter may be roughly placed at $\frac{I}{50}$ that of the earth, and the limit of individual volume at $\frac{I}{100000}$ that of the earth. Since the total mass must be an appreciable fraction of the mass of the earth the number of the hypothetical planets must be thousands and probably tens of thousands.

It may be suggested that in the zodiacal light we have evidence of at least the possibility that a group of many thousand bodies, too minute to be visible to the naked

A. P., PART VI--15

eye, circulate between the earth and the sun. It would be an interesting photometrical investigation to ascertain the limit of volume of these bodies of the supposition that they are of ordinary whiteness. The extreme softness of the zodiacal light is such that the minimum number of separate bodies would have to be estimated at hundreds of thousands. The writer thinks it probable that the result would be that a collection of 100,000 bodies with a combined volume one-tenth that of the earth would glow with a much brighter light than the zodiacal light actually does. The hypothesis of the zodiacal light is subject to the same difficulties with respect to motions of the nodes as have already been pointed out with respect to the group of planets. But we have at present no way of positively disproving it.

We may next inquire whether either a possible ellipticity of the sun or of his atmosphere, or of the matter in his interior, can produce the observed effect. The reply to this would be that the most exact measures have failed to show any ellipticity of the body of the sun at all approaching that required. Indeed, if we suppose the elliptic disturbance of matter, if I may use the expression, to be within the sun, it would probably be found that the consequent deviation of the level surfaces at the photosphere from a spherical form would lead to a sensible ellipticity of the sun's disk.

There is a field for investigation in the question what the mass of a ring round the sun must be to produce the observed effect, and what influence that mass would have upon the motion of the nodes of Mercury and Venus. This is a question which can be more profitably discussed when the character of the phenomena is more accurately ascertained. But, as the question now stands, all hypotheses that the observed phenomenon is produced by the attraction of unknown matter in the neighborhood of the sun or Mercury must be dismissed as at least highly improbable.

We may next inquire whether any deviation from or modification of the law of gravitation which would produce the observed effect is admissible. The most natural modification of this kind would be the addition of a term varying as the inverse third or fourth power of the distance. This hypothesis can, however, be refuted very readily. A term of the inverse third power which, at the distance of Mercury, should have a value even the millionth part of the total gravitative force of the sun would, at the distance of a foot, have a value two hundred thousand times that of the term depending on the inverse square. If higher powers than the cube were added the discrepancy would be yet more enormous. The existence of a term of such magnitude is out of the question.

Another hypothesis which has been considered in this connection is that of Weber's electro-dynamic theory. According to this theory the gravitative force between two bodies is expressed by an equation of the form

$$\frac{m}{r^2}\left(1-\frac{1}{h^2}\left(\frac{dr}{dt}\right)^2+\frac{2r}{h^2}\frac{d^2r}{dt^2}\right)$$

in which the constant h, as is evident from the formula, must be a velocity. This velocity Weber has sought to determine experimentally; his value is 439,450 kilometers per second. From this datum Tisserand has computed the secular variations of the planets.*

His results are that the only element affected with a sensible inequality is the perihelion, and that the secular motions of the perihelia of Mercury and Venus would have the following values:

If h be the velocity of light his result is,

But the actual motion has been found to be three times this. To produce this motion the value of h must be reduced to about 174,000 kilometers per second.

Objections have been raised to Weber's whole theory on the part of physicists, to whom the discussion of its possibility must be left.

Assuming that we are still to look to a more exact determination of the astronomical character of the phenemena for a solution of the question, the necessary steps are an exact determination of the mass of Venus from the periodic perturbations of the inner planets, an investigation of the secular motions of the planes of the orbits of these planets, and the comparison of the theoretical and observed secular motion of the perihelion of Venus.

The latter research would be of especial interest in this connection. Unfortunately, however, owing to the very small eccentricity of Venus, a motion of its perihelion amounting to only a few seconds in a century would escape the observations hitherto made. Moreover, the very imperfect way in which observations of Venus were made during the last century precludes our obtaining a satisfactory result. The question whether this element is effected by a motion corresponding to that of Mercury can, therefore, hardly be settled until after 20 or 30 years more of careful meridian observations of Venus. But a general investigation of the secular variations of all four of the inner planets might result in showing discordances which would throw some light on the question. This investigation is one for which the material is being prepared under the writer's direction.

§ 6.

Law of recurrence of transits of Mercury.

The conception of conjunction points, developed in Part I of the present series of papers, pages 8 to 10, enables us to lay down the law of recurrence of transits of Mercury in such a way that the times and circumstances of all possible transits during several centuries past and future may be determined with great ease. Since, however, we have to consider only those conjunctions which take place near the node, it will not be necessary to consider the arrangement and motion of the whole series of conjunction points. Moreover, it is only when we neglect the eccentricities that the conjunction points are uniformly distributed and move uniformly. The eccentricity of the orbit of Mercury is so great that the positions of the mean conjunction points give

us no index to the actual circumstances of transits. What we therefore have to do is to treat the relations of the sun and Mercury at each node separately, and consider their motions at this point as if they were mean motions. Notwithstanding the eccentricity and the secular motion of the perigee, the intervals between consecutive passages of each planet through either of the common nodes will be nearly the same for many centuries. These intervals will not, however, be the same for each node, nor will they coincide with the periods corresponding to the mean motions. By a simple computation from Leverrier's tables we find the following intervals between consecutive passages of the earth and Mercury through the common nodes during the first half of the present century:

Interval between passages of Mercury through the ascending node in No-

874.969204 Through descending node in May - - - - - - - - - -87^d.969046 Interval between successive passages of the earth through the ascending

365^d.254268 Interval for descending node in May - - - - - - - - - -365^d.254147

If we develop the ratio of each of these pairs of periods as a continued fraction, we have the following results:

Proof the ratio of each of these pairs of periods as a corlowing results:

NOVEMBER.

Ratio of Periods =
$$\frac{1}{4 + \frac{1}{6 + \frac{1}{1 + \frac{1}{1 + \frac{1}{2 + \frac{1}{1 + \frac{1}{1 + \frac{1}{3 \cdot \frac{9}{11}}}}}}$$

Ratio of Periods =
$$\frac{\frac{1}{4 + \frac{1}{6 + \frac{1}{1 + \frac{1}{2 + \frac{1}{4 \cdot \frac{16}{16\overline{1}}}}}}{1 + \frac{1}{4 \cdot \frac{16}{16\overline{1}}}}$$
rging fractions for each period, so far as it is necessary to

The converging fractions for each period, so far as it is necessary to carry them for our present purpose, are

$$\frac{1}{4}$$
, $\frac{6}{25}$, $\frac{7}{29}$, $\frac{13}{54}$, $\frac{33}{137}$, $\frac{46}{191}$, $\frac{171}{710}$, $\frac{217}{901}$.

These fractions are common to the extent to which we have carried them, but beyond this point we should have different convergents for May and November.

The first ratio to be considered is 46:191. It shows that at the end of forty-six years Mercury will have made nearly 191 revolutions, so that the two bodies will

have returned nearly to their original positions. The number of conjunctions will have been 145, which is therefore the number of conjunction points when this system is adopted. In order that each conjunction may occur at one of these 145 points, we must attribute a suitable motion to the whole system. This motion may be best conceived by determining the intervals between consecutive passages of the conjunction points through the node, an interval which is given by the equation .

$$I = \prod_{i \mid T - i' \mid T'}^{T \mid T'}$$

T and T' being the periodic times of Mercury and the earth, respectively, and i and i' the chosen coefficients; in the present case 191 and 46.

From the preceding values of T and T' we have

```
191 T for November - - - - = 16802.1179

May - - - - - = 16802.0877

46 T' for November - - - - = 16801.6963

May - - - - - - = 16801.6908
```

We thus find:

For November transits - - - I \equiv 208.6 years. For May transits - - - - I \equiv 221.6 years.

The value of I for November is gradually increasing, and that for May gradually diminishing, in consequence of the secular recession of the perihelion from the node.

The last passage of a November conjunction point through the ascending node occurred about the year 1776. The adjacent point will therefore pass the node about the year 1985. At the present time, 1882, the node is about half way between these points. The limits within which a November transit may occur are distant a little more than four intervals between conjunction points. Hence, at the present time, four transits occur during each 46-year period.

The last passage of a May conjunction point through the descending node occurred about 1725; the next will therefore occur about 1946. Only two May transits can occur during the 46-year period.

The conditions under which transits will recur for several centuries may be conceived by the following scheme. The horizontal lines are those along which Mercury may be supposed to pass as it crosses the several conjunction points. The planet must be supposed to pass along each of these lines in November of every 46th year, in an indefinite series. The dates of several passages are given at the right of the line, and the series may be continued at pleasure in either direction.

Thirty-three years after passing each line it passes along the next line below. Thirteen years after passing each line it passes along the line next above. Thus all the passages along these six lines may be indefinitely continued, and additional lines may be added above and below.

The sun must be supposed to move downward across the lines at such a rate that it passes over the space between two lines in 208.6 years. The line on the left represents the sun's vertical diameter, the position being that which it occupies in 1800. Its length is about $4\frac{1}{10}$ spaces between the horizontal lines. Its downward motion is

such that the north end passed the first conjunction point about 1794, and its south end crossed the fifth conjunction point about 1764. The passages of each end over the conjunction lines are given on the diagrams, the intervals being 208.6 years, with a minute increase in future centuries. These motions being supposed, we have the following rule for predicting transits. Every time that the planet in its passage along a conjunction line strikes the sun's diameter there will be a transit across the disk.

If it passes near the end of the diameter without striking it there will be a near approach to the sun. If the passage across the transit occurs near the center of the diameter, the transit will be a nearly central one. Thus one can, in a few minutes, map out all the transits and all the near approaches to the sun which are to occur for several thousand years, with a close approach to precision. It will be noticed that there is for each conjunction point a period of 864 years, during which the sun is in such a position that the planet will strike it at each passage. By continuing the series the limiting dates can thus be computed for each point. The dates of passage of Mercury along each line are found by adding to any one line the quantity 33 + 46 i years to form the dates for the lines next below. Here i may be any integer. We thus have belonging to each line an indefinite system of numbers, congruous with respect to the modulus 46. Such of these numbers as fall within the interval of 865 years between the two dates above the line will correspond to transits of the planet. The first date of the series will be very near the south limb. A date corresponding exactly to that given on the line will indicate a case in which the planet grazes the sun's limb: dates outside of the interval will indicate approaches more or less near the limb. The successive transits will then occur nearer and nearer the sun's center for a period of four centuries, when the line will pass the center and the following ones of the series will occur near the north limb.

Scheme for November transits. Transit of Transit of South Limb of ① North Limb of O 1644, 1690, 1736, 1782, 1828, etc. N. 1138 1677, 1723, 1769, 1815, 1861, etc. 1347 1710, 1756, 1802, 1848, 1894, etc. Node in 1800 1555 Ö, 1743, 1789, 1835, 1881, 1927, etc. 1764 1776, 1822, 1868, 1914, 1960, etc. s. 1973 1993, 2039, 2085, 2131, 2177, etc. 2181 - 2164, 2210, 2256, 2302, 2348, etc.

The corresponding scheme for May transits is given below. The two points in which the schemes differ is that the thirty-three years' interval is measured in the opposite direction from that of the November transits. The motion of the node being also reversed, the diagram itself is inverted, so that the motion shall be downward. The north end of the sun's diameter is the lower one. Moreover the length of the diameter line instead of being equal to four spaces between the horizontal lines, is equal to a little less than two.

The successive transits are now determined in the same way as the November ones, but owing to the diminished relative length of the sun's diameter there will be fewer transits along each line. Moreover the first transit of each series will occur near the sun's north limb.

Scheme for May transits. Transit of Transit of North Limb South Limb of O ol O 1285 1628, 1674, 1720, etc. 1506 1707, 1753, 1799, 1845, 1891, etc. Node in 1800 1728 1740, 1786, 1832, 1878, 1924, etc. 1950 1957, 2003, 2049, 2095, 2141, etc. 2171 2174, 2220, 2266, 2312, 2358, etc. 2393 2391, 2437, 2483, 2529, 2575, etc. 2614 - 2608, 2654, 2700, 2746, 2792, etc.

The next higher system of conjunction points which it is advantageous to consider is that corresponding to the ratio 217:901. This ratio is obtained by supposing the last denominator of each continued fraction to be 4. It expresses so nearly the relative motion of the earth and Mercury from their common node, that it is a little too great for the one node and a little too small for the other. The corresponding number of conjunction points is 684. We may therefore say that, as a rule, 217 years after each transit there will be another transit over the same part of the solar disk.

Two plates are appended hereto showing the apparent paths of Mercury over the disk of the sun during all the transits from 1667 to 1881 inclusive, which constitute one series of 217 years. At the end of this period the transits are repeated. To find the slight deviation of the new series from the old one, we note that the last denominator $\left(4-\frac{2}{11}\right)$ in the continued fraction expressing the ratio for the November transits.

sits, shows that at the end of the period the remaining transit will fall about \$\frac{1}{6}\$ of the 46 years' interval below the transit 217 years preceding. These recurring transits are shown by two dotted lines near the points of egress and ingress with the corresponding years.

In the case of May transits the fraction is about $\frac{I}{IO_1}$ so that the coincidence will

be relatively closer. The diagrams give all the transits within the interval, whether observed or not. Those which have not been observed are indicated by dotted lines. In cases where only one of the phases, egress or ingress, has been observed, one-half of the line is dotted and the other half is left entire.

In the case of the past and future series of May transits, namely, those before 1707 and those after 1881, it may be remarked that the dates are on the wrong side of the lines. For instance, in 1924 the path will be a little north of what it was in 1707. Neglecting inequalities, the change should be one-tenth the space between two consecutive paths.

The times given on each path are those of the middle of the transit. In the case of observed transits these times are the actual means, to the nearest minute, between internal contact at ingress and at egress. They are, therefore, affected by small inequalities arising from periodic perturbations by Venus and the other planets. In the case of November transits these perturbations rarely amount to a minute, so that they do not materially affect the progression of the given times. But in the case of a May transit the effect may amount to several minutes. In the case of transits which have not been observed, no computation of the times has been made, but the times as given are derived by induction from the transits preceding and following.

The times of beginning and ending may be obtained by subtracting and adding the semi-duration from or to the middle times given on the diagram. A scale at the bottom of each diagram will enable us to determine the duration of any transit within one or two minutes. To do this we take in a pair of dividers the length of the chord described by the planet on the diagram, and find the corresponding time on the scale. This time will be the duration from internal contact at ingress to internal contact at egress. It may be expected that the times of egress and ingress thus found will not, for several centuries, be more than three or four minutes in error for the November transits, nor more than five or six minutes for the May transits. Of course the errors may be greater when the chord is very short.

In the case of transits outside the period 1677-1881 the diagrams give only the years. But the times, within a few minutes, may be found by adding to each time during the given period:

79260^d 6^h 24^m for November transits. 79260^d 2^h 10^m for May transits. We thus find the following approximate Greenwich mean times of middle of transit for the period beginning with 1891:

Remarkable transits.—By the aid of the diagrams we are enabled on sight to select transits which are remarkable from any circumstance and to determine those which are visible in any longitude.

During the last two centuries the transits in which Mercury passed at the shortest distance within the sun's limb are those of 1776, November 2, and 1782, November 12. The two transits correspond closely in their general features, but they occurred near opposite limbs of the sun. That of 1782 was fully observed both in Europe and America. The other does not however seem to have been observed at all, although the ingress at least was visible throughout the United States, and the whole transit in the Middle and Southern States.

Following up the series of transits, which commenced with that of 1776, at intervals of forty-six years, we find the duration longer and longer. The next transit of the series will occur 1914, November 7, when the path of Mercury will be nearly the same as it was on 1697, November 2.

Among the unobserved transits it is most surprising that that of 1835 appears to have passed unnoticed, although the ingress was visible all over the United States, it having occurred about Washington noon.

The next occasion on which a November transit as near the sun's limb as those of 1776 and 1782 will occur is 1999, when it is probable that Mercury will barely enter upon the sun's northern limb.

In the case of the May transits there will be no remarkably short transit for a number of centuries. That of 1957 will probably be the shortest during the next 300 years. But on the morning of 1937, May 11, Mercury will pass so close to the sun at inferior conjunction that it may almost be seen projected on the chromosphere. The nearest approach to the sun's limb cannot be given without a more careful computation from the tables. It is however certain that it will be only a little more than a minute of arc. The path laid down on the diagram is obtained by simple measurement, and is therefore somewhat uncertain.

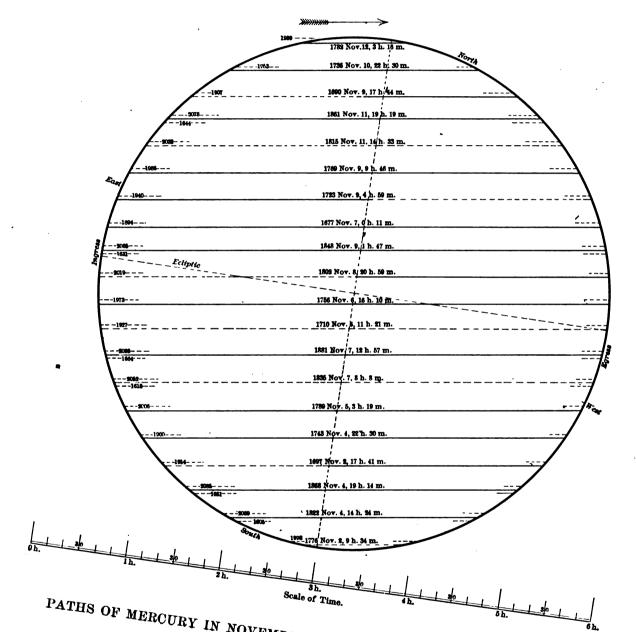

Until the question of possible changes in the earth's axial rotation shall be placed on a firm basis, or until the theory of the moon's mean motion shall be so perfected that these changes can be determined with precision from observations of that satellite, transits of Mercury must be regarded with the greatest interest as affording independent determinations of the variations in question. The November transits will long be most favorable for this purpose, for the reason that the series of observed November transits extends back nearly a century before the first well-observed May transit. It is to them therefore that we must principally look for light upon this question. The next November transit will be that of 1894. It will be very favorable for this purpose because it is not far from central. Ingress will be visible over the American continent, and egress at points west of the Alleghenies. The transits of 1907 and 1914 will be less favorable on account of being nearer the limb of the sun. That of 1927 will however be again favorable, and, in may be hoped, will decide the question at issue.

CORRIGENDA.

Page 384. Reduction to geocentric phase for contacts I and II, for $+29^4$.2 read -25^4 .1, and carry the correction forward. Page 405, Reduction for Altona, for $+58^4$ read $+54^4$, and carry the correction forward.

Page 406, Contacts II, for 2th 3m 32t read 2th 3m 30t.

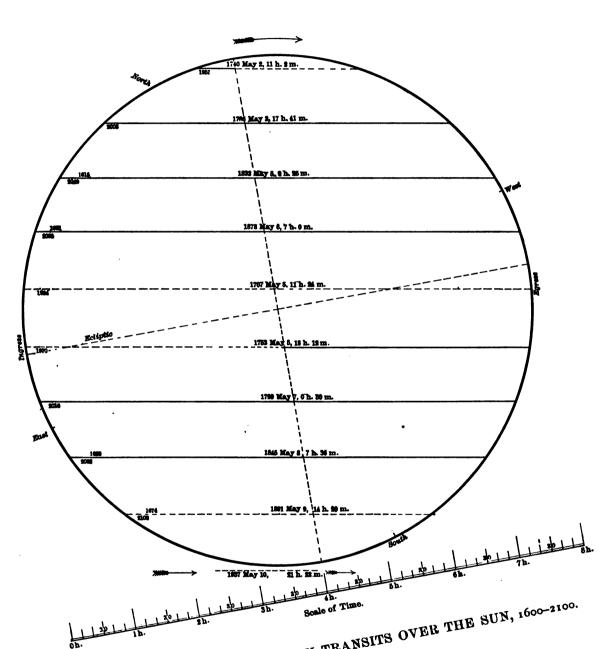

It is also to be remarked that the list of longitudes beginning on p. 374 does not, in all cases, give the longitude of the station actually adopted, it having been sent to press in an imperfect state.
